GRASS INSTRUMENT CO.

101 OLD COLONY AVE

QUINCY, MASS

PR3 0002

A COMPLETELY AUTOMATIC UNIVERSAL OPTICAL RECORDER

FOR PHOTOGRAPHING
MOTION STROBOSCOPICALLY
CELL OR PLANT GROWTH
CATHODE-RAY
and/or
MOVING LIGHT BEAM

KYMOGRAPH CAMERA MODEL C4-A

Application Although designed primarily for Electrophysiology, the use of the Kymograph Camera is by no means limited to this field. In the applications listed above, its synchronizing and controlling circuits determine automatically the sequential operation of associated devices such as stimulus, cathode-ray sweep, stroboscopic flash, film advance, shutter opening, etc

Frame Advance Control by manual switch or external circuit giving single frame advance or repetitive frame advances at rates from 1/min to 4/sec

Continuously Moving Film Speeds Twelve fixed speeds from 0.25 to 1000 mm/sec $\pm 0.5\%$, all in convenient divisible numbers (1000, 500, 250 etc). Film attains full speed and comes to a stop within 20 milliseconds (about 20 mm of film at maximum speed), thus avoiding film wastage. The duration of film

exposure can be controlled internally up to $\frac{1}{2}$ sec and externally for longer times

Recording Materials 35 mm film or paper, preferably unperforated for oscillographic work, thus giving 60% more image area for full frame exposures

Optical System 50 mm Wollensak f-2 lens in self-cocking Synchro-shutter. Prism allows viewing image without loss of film, and recording by moving light beam from the side (such as a mechanical myograph) simultaneously with conventional photographic recording from the front lens

Magazines 200 ft capacity. Independently removable with automatically closing gates, allowing take-up magazine to be removed for developing partial spools without exposure of remaining film.

Mounting Film may be run vertically or horizontally by using quickly interchangeable mount

MAKERS OF ELECTROENCEPHALOGRAPHS AND
ELECTROPHYSIOLOGICAL INSTRUMENTS SINCE 1935

A H T CO SPECIFICATION

BARCROFT-WARBURG APPARATUS

Operating constancy $\pm 0.03^{\circ}\text{C}$, suitable for continuous service

Double Clutch Attachment, now available, for independent operation of one set of 7 manometers on one side of a 14-unit outfit, thereby permitting reading of one set without interruption of shaking of opposite set

Can be attached in the laboratory to A H T Co Baths now in use

Price \$80.00

3604-A

BARCROFT-WARBURG APPARATUS, A H T Co Specification Incorporating suggestions of Dr Eric G Ball, while in the Laboratory of Physiological Chemistry, Johns Hopkins School of Medicine. For the measurement of cell respiration and similar processes which depend on reactions wherein a gas is either absorbed or evolved under carefully controlled conditions, but also suitable for almost any macro or micro analytical procedure involving kinetic gas exchanges

Consisting of sets of seven or fourteen Barcroft-Warburg Manometers of glass with standard taper interchangeable ground joints mounted on improved type aluminum supports with white background behind the graduations and $24\frac{1}{4}$ inches long X 15 inches wide X 10 inches deep, with mercury in glass type thermo-regulator adjusted for 37°C and sensitive to changes of 0.03°C equipped with electric shaking and stirring devices, immersion heater, special thermometer 36 to 40°C in $1/20^{\circ}$ divisions, reading lamp on extension cord, and slotted wooden base for supporting seven manometers in vertical position when not in use. Manometers are shaken in a vertical position on ball bearing rollers. The speed of the shaking device is controlled by a rheostat, as is also the speed of the stirring unit.

3603 Barcroft-Warburg Apparatus, A H T Co Specification Seven-unit, complete as above described, adjusted for 37°C including seven manometers on improved aluminum supports, constant temperature bath with shaking and stirring devices, immersion heater, thermo regulator, special thermometer reading to $1/20^{\circ}\text{C}$, a.c. 603 00

Note—Can be converted into a fourteen-unit assembly by addition of accessories offered separately

3604-A Ditto Fourteen-Unit, identical with above but with fourteen manometers and two slotted wooden bases each for seven manometers. For 115 volts a.c. 883 00

FEDERATION PROCEEDINGS is published quarterly by the Federation of American Societies for Experimental Biology. The *March* issue consists of the Program (Part II) of the Annual Meeting of the Federation, and the Abstracts (Part I) of the papers presented at the scientific sessions. Both parts include an author index. The abstracts are arranged alphabetically according to the first author and segregated as to Societies. The *June* and *September* issues contain symposia and other special papers presented at Federation meetings as selected by the Editorial Board. The *December* issue contains the membership list and other matters pertinent to the Constituent Societies of the Federation.

Price Schedule

The subscription price is \$4.50 (\$5.25 foreign) payable in advance. Single issues may be purchased, if ordered in advance, at the following prices: No. 1 (Part I, March, Abstracts), \$3.00; No. 1 (Part II, March, Program), 75¢; Nos. 2 and 3 (June and September), \$1.50 an issue; No. 4 (December), \$2.25 an issue. Subscriptions and orders should be sent to the Federation of American Societies for Experimental Biology, 2101 Constitution Ave., Washington 25, D. C.

Entered as second class matter March 16, 1942, at the Post Office at Baltimore, Maryland, under the Act of August 24, 1912.

Made in the United States of America

days **become** *hours*

Think back to the time when you were completely dependent on manual methods for histologic processing. Tissue preparation that frequently took days to do then is now done in a matter of hours. Everybody's time is saved: technician's, pathologist's, surgeon's, patient's, and hospital's. Tissues come through faster and better — diagnosis is prompter. The working day becomes more productive.

This is why thousands of hospitals all over the world depend, with justified confidence, on their Autotechnicons for unfailing, day-in, day-out service.

NEW PRICE SCHEDULE

Federation Proceedings

Effective with Volume 11 (1952) the subscription price for **FEDERATION PROCEEDINGS** will be \$6 00 per year

The new price schedule is as follows

Subscription prices

United States and Countries of the Postal Union	\$6 00
Canada	6 25
Other Countries	6 50

Single issues, when available, may be ordered as follows

Vol 11, No 1, Part I, March (Abstracts)	\$3 00
Vol 11, No 1, Part II, March (Program)	1 00
Vol 11, No 2, June	2 00
Vol 11, No 3, September	2 00
Vol 11, No 4, December	3 00

Orders are payable in advance. Please address inquiries to **FEDERATION PROCEEDINGS**, 2101 Constitution Avenue, Washington 25, D C

Notice

To Subscribers

RESERVE STOCKS of the following back issues of FEDERATION PROCEEDINGS are very low or exhausted

VOLUME 1, No 3, September 1942
 VOLUME 1, No 4, December 1942
 VOLUME 4, No 4, December 1945
 VOLUME 5, No 1, Part I, March 1946
 VOLUME 5, No 2, June 1946
 VOLUME 5, No 3, September 1946

Requests for complete sets of FEDERATION PROCEEDINGS from new subscribers and libraries abroad are received continually. Members and subscribers who have copies of any of the above issues and who do not wish to retain them will render a distinct service to the Federation and to their scientific colleagues by sending such issues by mail or express to FEDERATION PROCEEDINGS, 2101 Constitution Avenue, Washington 25, D C

Volume 7, No 1 (both Program and Abstracts for 1948), which has been out of stock for the past two years, is now available and may be ordered from the Washington Office of FEDERATION PROCEEDINGS

Sedimentation Rates Valuable Adjunct in Diagnosis

Blood sedimentation tests are well-established laboratory procedures. As long ago as 1797, it was first noted that inflammatory processes increased the sedimentation rate of red blood cells. Explanations of this phenomenon vary, but there is little doubt that sedimentation rates can provide an excellent clue to the presence or absence of an inflammatory process. In some cases, the sedimentation rate is an accurate indication of the severity of the infection.

Generally, changes in sedimentation rate are a more sensitive indicator than body temperature, and many investigators have published detailed studies on these changes in various infectious conditions. The sedimentation rate is a particularly valuable indicator in tuberculosis, pelvic inflammatory disease, rheumatic fever, infectious arthritis, pneumonia, Hodgkin's disease and acute coronary thrombosis.

In general practice, the sedimentation rate has three important practical applications:

- 1—Indicates the presence of inflammatory process
- 2—Indicates the activity and progress of the condition

- 3—Aids in differential diagnosis. Studies have shown characteristic sedimentation rates for conditions whose initial symptoms are non-specific.

Methods now available for determining sedimentation rates include macromethods, the most popular of these being Wintrobe, Westergren, Cutler and Linzenmeier, in which blood is withdrawn by venipuncture. In the Landau-

Landau-Adams Microsedimentation Apparatus

Adams, which is a micromethod, only a drop or two of blood, which may be taken from the fingertip, is required. The latter is particularly suited for corpulent adults and children, where it is often difficult to do a venipuncture, or in any case where repeated blood withdrawals are contemplated.

A leaflet describing the various apparatus and methods for blood sedimentation is available on request.

Experimental Procedures Utilize Polyethylene

Biologists attending the recent Cleveland meeting of the Federation of American Societies for Experimental Biology showed great interest in the adaptability of polyethylene tubing to various experimental procedures in physiology and surgery. Clay-Adams animal-tested Polyethylene Tubing is available in 23 sizes ranging from inside diameters of .011" to .500"—small enough to cannulize a vein in a bat's wing, or large enough to replace a dog's aorta. Because it is free from tissue reaction, Clay-Adams polyethylene tubing may be left in the body without side reactions.

MICRO SLIDES AND COVER GLASSES

Special Glass, Precision Methods Insure Gold Seal Quality

Careful, accurate and uniform manufacturing processes make Clay-Adams GOLD SEAL Slides and Cover Glasses leaders in their fields

GOLD SEAL Microscope Cover Glasses are made of special hand-blown glass of extreme hardness. The glass blanks from which the cover glasses are cut come in large, thin sheets of varying thickness. Trained technicians carefully gauge each section of the glass and mark off pieces of uniform thickness. The glass sheets are also inspected for irregularities such as bubbles, striae and cracks. A surprisingly large

UNRETOUCHED PHOTO shows effect of time on an ordinary (L) and a GOLD SEAL cover glass

percentage of glass per pound is rejected as unfit. This careful processing guarantees that, within a given thickness, the user gets more cover glasses per ounce.

GOLD SEAL Micro Slides are made to similar rigid specifications. For years they have been the standard for comparison among the country's leading histologists. Each slide is carefully inspected to detect all defects and imperfections. Edges are carefully ground and polished.

Even after years of use, GOLD SEAL Slides and Cover Glasses will not corrode or fog (see illustration).

GOLD SEAL Slides and Cover Glasses are available in various sizes of squares, rectangles and circles.

Simple Gastrectomy Tube for Feeding and Drainage

The Einhorn Simultaneous Bilumen Gastrectomy Tube affords a simple method for simultaneous or independent jejunal feeding or drainage and gastric drainage. The tube is simple to insert or withdraw, since it is bucketless. It is introduced through the nose prior to the operation, and slipped into the jejunum after anastomosis.

The Einhorn Gastrectomy Tube is 48" long, bisected by a center wall to give a double semi-circular lumen. Each lumen can be used separately since they have separate openings at both ends. The shorter lumen opens into the stomach 14½" above the end of the tube. The tip of the tube is weighted for smooth and easy passage.

nuclear

Radioactive Chemicals

NUCLEAR radioactive chemicals, now available to A E C.—authorized users, represent another step toward the NUCLEAR aim of *complete* service in nucleonics for science and industry. As the only commercial producer of biosynthetically labeled compounds, NUCLEAR is prepared to fill the needs of those experimenting or contemplating work in this vast new research field

BIOSYNTHESIZED C¹⁴ LABELED COMPOUNDS NOW AVAILABLE FROM STOCK

Glucose • Sucrose • Fructose • Starch

Characteristics

- Chemically pure
- Uniformly labeled with C¹⁴
- Specific activity

Normally, 0.5 microcuries/milligram
(Higher specific activities by special request)

Nuclear is also making chemically synthesized compounds such as carboxyl labeled Sodium Acetate — other special compounds to be announced Write to NUCLEAR for details on radioactive compounds

Complete service for both new and established laboratories—help on isotope procurement, authorizations, laboratory layout, and equipment facilities

nuclear INSTRUMENT & CHEMICAL CORPORATION

241 West Erie Street • Chicago 10, Illinois • Cable Address: Arlab New York

- Scaling Units for Every Type of Radiation Counting
- Complete "Packaged" Counting Systems
- Health Monitoring Instruments for Personnel Protection
- Glass Wall, Mica Window and Windowless Counters
- Portable Count Rate Meters
- Radioactive Chemicals
- Complete Line of Accessories for the Nuclear Laboratory

de Fonbrune micromanipulator

*Has Smooth, Uniform
Pneumatic Movement*

Affords new simplicity and flexibility for micro-studies in biological or chemical technics

Improved de Fonbrune Micro-Forge With Binocular Body

Specifically developed for use in the fabrication of simple and intricate micro-tools of glass or metal under controlled conditions. Use of the de Fonbrune micro-forge is recommended with any type micromanipulator. The forge is now built with binocular stereoscopic microscope. With this modification, the image is observed erect—not inverted—in three dimensions, an important factor in rapid, accurate work.

The de Fonbrune micromanipulator, incorporating a pneumatic pump system, has proved exceptionally satisfactory for micro-studies in many fields. In the biological sciences the de Fonbrune instrument is used in cell dissection and isolation, micro-injection and operation on the protozoa, pH studies on living cells, isolation and transfer of single bacteria, etc. This flexible instrument has proved equally serviceable in study of fibers and yeast cells, in investigating oils, rust deposits, colloidal, and other materials.

Manufactured under exclusive license of the French patents, the de Fonbrune micromanipulator consists of a manipulator and receiver. These units may be used with any type of microscope arranged for right or left hand operation. In use, the micro-tool is mounted on the receiver. Impulses from the pneumatic pumps of the manipulator are transmitted to the tool through sensitive metallic membranes. Within a range of 3 mm, the micro-instrument may be moved in any plane or angle by a single control. Ratio of displacement of control lever and micro-tool may be adjusted from 1:50 to 1:2,500 depending on range desired.

ANNOUNCING A NEW INSTRUMENT for research and routine **POLAROGRAPHY**

a PATWIN Instrument

Designed to fill the growing need for a precise, reliable and stable manual polarographic instrument will measure all the fundamental characteristics of a dropping mercury electrode system (such as half-wave potentials and diffusion currents) in absolute terms and with high precision. Such a calibrated instrument is of utmost importance in routine work when complete waves are not obtained. It may also be used as an accurate potentiometer wherever an electrometer is not necessary. **ONLY** instrument with all these features:

- 25 turn helical potentiometer accurate to 0.1%, reading to one millivolt with a span voltage of 2.5 v — and to double this value at a span voltage of 5.0 v
- Self-contained standard cell and standard resistors for calibrating
- Low resistance galvanometer with sensitivity approximating 0.005 microamperes per millimeter. Multiple shunt from 1 x to 300 x. Scale length 320 mm

USES

Metals
Alloys
Ores
Plating solutions
Boiler water
Corrosion studies
Paints
Explosives
Petroleum
Gasoline
Oils and soaps
Sugar products
Dyes/stuffs
Albumins
Amino acids
Alcohols
Ketones
Serums
Proteins
Alkaloids

Federation Placement Service

To MEET THE NEEDS of employers and of individuals seeking positions in the fields of the Federated Societies, the Placement Service maintains the following activities:

- 1 Listing positions, fellowships and exchanges
- 2 Listing applications for positions from qualified individuals
- 3 Publishing, *quarterly*, lists of applicants, *semiannually*, lists of available positions, and, *annually*, a list of fellowship and exchange positions
- 4 Providing registration and interview services at the annual meeting

In order to maintain and expand these activities so that they may give maximum service to members of the Federation, it has become necessary to take steps towards increasing the income of the Placement Service. The Executive Committee at the 1951 annual meeting authorized the following scale of charges:

Annual subscription to all lists of the Service	\$10.00
Single copy of any one list published	5.00
Annual applicant registration fee	3.00

To obtain registration cards or enter subscriptions, address

for rapid quantitative determination
of SODIUM and POTASSIUM

the BARCLAY FLAME PHOTOMETER

a **PATWIN** Instrument

Combines operating simplicity with variable sensitivity and a very high order of accuracy over a wide range of concentrations. Features include

Outstanding performance requires only 10.0 ml sample, detects down to 0.1 ppm (2×10^{-3} Meq/L.) of potassium, even lower for sodium

Precision Design eliminates build up of salts and inside of burner surface, stainless steel atomizer needles provide uniform orifice for stable operation. Built in air pressure regulators with indicating gauges for positive and accurate control

Sloping Panel — easy to read durable all metal case with gray hammer-tone finish 28" x 18" x 16" high

Convenience of operation all components within easy reach. Atomizer accessible for manipulation and cleaning. Easily connected to air and gas services

Low maintenance simple internal DC circuit — only external connection required is for galvanometer

Wide application in the fields of—
Agricultural chemistry
Chemical industry and education
Food technology & water treatment
Clinical and medical routine testing and research.

Atomizer accessible for cleaning

the new

textbook
of
biochemistry

by West and Todd

Never before has a textbook so fully outlined the principles of physical and organic chemistry upon which biochemistry is based, and then presented the essentials with clinical application in view. Here, nutrition in all its important aspects is covered, and isotopic methodology and results obtained therefrom are included. This text is liberally provided with summaries, charts, and dia-

grams enabling the student to obtain information quickly. The subject matter throughout is so developed that the student will have a reliable guide through the vastly complex and growing science that is biochemistry, and he will clearly see what roads are open for further research.

FRACTIONATION PROBLEMS?

here's help for you . . .

THIS tireless servant in your laboratory will automatically collect any number (up to 200) of rigidly controlled samples of predetermined fluid volumes. Each collected sample may comprise any number of drops from one to four hundred. As each separate sampling is completed, the carriage automatically advances to repeat identical collections consecutively until the whole fractionation has been made.

All you have to do is to set it up for the conditions of the chosen experiment, short or long, and then leave it alone. The machine will plod along without attention hour after hour, all day (and night) long. When the job's done, it will shut itself off.

The Technicon Fraction Collector has been thoroughly tested in actual laboratory installations, where it has proven invaluable to busy research staffs. We shall be happy to send you details.

Ref. Chromatography of Amino Acids on Starch Columns—
W. H. Stein and S. Moore, *Jrnl Biol Chem* 176, 337, (1948)

saves time and labor

relieves laboratory staff of the fretful and time-consuming chore of fraction-cutting releases workers for other duties

triples work output

you can run it twenty-four hours a day, continuously, to triple fractionation output as compared with an 8 hour laboratory day

gives greater resolution

by collecting a large number of small fractions, rather than a few gross ones, you'll get more data from a given fractionation, e.g. a chromatogram, or a fractional distillation

assures accuracy

because the possibility of human error is automatically ruled out. Now fraction-collection becomes a straightforward mechanical procedure

Complete Epileptic Seizure-control, First Step in Rehabilitation

In the drug therapy of the epileptic, nothing short of *complete* suppression of seizures can rightly be called full success. Complete seizure control is a prerequisite to the patient's return to a normally active life. Carter¹ states:

Basically all efforts should be directed toward preventing seizures and the tendency to chronic invalidism.

The management regimen should include¹

- I Good physical and mental hygiene
 - a) Wholesome diet, Regular bowel habits, Avoid noxious materials, e.g. alcoholics, Moderate physical activity
 - b) Help overcome feeling that epilepsy is shameful, Encourage normal work and recreation, Regular sleep without overprotection

II Anticonvulsant medication selected on the basis of Exact Diagnosis

'Certain drugs are more effective in one type of seizure than they are in another, and it is necessary to use proper drugs. The dosage must be individualized for each case.'¹

Thus, the best guide in selecting medication for a patient is the type of seizures present. (Frequently several drugs in combination is most effective.)

The table shows which drugs are indicated for each type

of seizure. It will be noted that the newer hydantoin, Mesantoin, is effective for *grand mal*, Jacksonian and focal seizures.

MESANTOIN DOSAGE is adjusted to the lowest level adequate to attain freedom from seizures. Start with 1/2 or 1 tablet daily during the first week, increase the daily intake by 1/2 or 1 tablet during the next week. Continue this up to optimal dosage. When another drug has not given good results, Mesantoin is added by the same procedure, then the old drug is gradually reduced.

SIDE EFFECTS—Mesantoin produces side effects in some cases. Skin and blood changes are signs of sensitivity—the drug should be discontinued. Drowsiness develops upon reaching maximum dosage.

PRECAUTIONS—Certain precautions are necessary to minimize untoward effects:

- a close check on patient—repeated visits and blood counts
- b No Mesantoin, if white cell count below 4000
- c caution if (1) rash or blood changes
(2) History of drug sensitivity
- d discontinue drug if (1) bleeding of gums or vagina
(2) Sore throat

TYPE OF EPILEPSY	PRIMARY CLINICAL MANIFESTATIONS	MEDICATION	AVERAGE ADULT DAILY DOSE*	LIMITING SIDE EFFECTS	SIGNS OF SENSITIVITY
GRAND MAL	Aura followed by loss of consciousness, tonic clonic convulsions and autonomic disturbance e.g., in bladder function.	-Phenobarbital	1 1/4 grs h.s. Usual max 3 grs per day	Sleepiness	
		-5,5 diphenyl hydantoin	1 1/4 grs t.i.d. p.c. Usual max 6 grs per day	Diplopia, staggering (may increase petit mal)	Overgrowth of gums, body hairs, itching, rash on extremities, gastric irritation
JACKSONIAN	Convulsions begin in one area and spread outwards (Jacksonian march). No loss of consciousness. ²	-3 methyl 5 5 phenylethyl hydantoin (mesantoin)	Adults 2 to 6 tabs Children 1 to 4 tabs	Sleepiness	For full details see Psychomotor cross column below
		-phenylacetylurea ³	2 Gms per day Max dose 6 Gms per day ³	Drowsiness	Central nervous system affected, nausea, vomiting and abdominal pain ⁵
PSYCHOMOTOR	Period of amnesia, actions apparently purposeful but mechanical, incoordination. Mild tonic spasms. In children 'behavior problems'. ³	-3 methyl 5 5 phenylethyl hydantoin ⁴ (mesantoin)	Adults 2-6 tabs Children 1-4 tabs	Pharyngitis, mucous membrane bleeding, lymphadenopathy, measles like rash with itching and fever in severe reaction, blood dyscrasia	
		-phenylacetylurea ³	See phenylacetylurea—above		
PETIT MAL TRIAD	Attacks in series (rapid succession), abrupt onset, few sec. duration, no aura nor impairment of consciousness. Rhythmic twitching (e.g. eyelids).	-3 5 5 trimethyl oxazolidine 2,4 dione	0.9 to 1.2 Gms	Inability to see in a bright light, Drowsiness	Hiccough, acneiform rash, leukopenia
		-N methyl derivative of phenobarbital	6 grs	Sleepiness	

*Although an average daily dose can be stated for each of these drugs, to obtain best results it is necessary that the physician determine the dose required by each individual patient for maximum control of his seizures.

CARBO-RESIN

(SODIUM REMOVING RESINS LILLY)

begins a new era of edema control

Ordinary table salt, so necessary to the acceptability of food, may now be permitted more liberally to patients with acute congestive heart failure and to others whose retention of sodium is excessive

The two cation exchange resins in 'Carbo-Resin' capture and effectively remove undesired sodium. One of them also prevents the depletion of potassium by making a supply available for absorption. An additional ingredient, a special anion exchange resin, helps the other resins to remove more sodium. Moreover, it is especially important because it lessens the hazard of acidosis that may occur when cation resins are used alone.

Edema may be controlled by 'Carbo-Resin' with only moderate restriction of sodium. This new regimen makes it possible for injections of diuretics to be given less frequently or often eliminated. In those cases in which mercurials are contraindicated, 'Carbo-Resin' can provide an alternate treatment.

Details on dosage and other important information on 'Carbo-Resin' may be obtained from your Lilly medical service representative or by writing to

ELI LILLY AND COMPANY • INDIANAPOLIS 6, INDIANA, U S A

The American Chemical Society, like Eli Lilly and Company, is now celebrating its seventy fifth anniversary, and we pause to pay it tribute. Our own industry, as well as all of American progress and humanity, is deeply indebted to this esteemed group of scientists.

MECHANISMS OF BIOLOGICAL EFFECTS OF PENETRATING RADIATIONS

CORNELIUS A. TOBIAS¹

From the Donner Laboratory, Division of Medical Physics, University of California, Berkeley

TO THE biophysicist, the study of the biological effects of penetrating radiation is a particularly interesting field because of the intimate connection of the radiation effect with the problem of growth. I wish to mention a few of the unique properties of radiations.

First, some radiations can penetrate the cell wall and interact with internal components of cells. The cell wall provides protection against many chemical agents.

Secondly, radiation seems to inhibit the mechanisms controlling growth before it seriously interferes with other cell functions. Radiation thus becomes a suitable tool for study of cell division.

Thirdly, the amount of energy which the cell must absorb if cell division is to be inhibited is extremely small compared to the energy turnover of the cell as a machine, or compared to the amount of energy needed from other sources to cause lethal effect. For example, many cells are inactivated by an amount of penetrating radiation which, as heat, would be only sufficient to raise cell temperature by a few thousandths of a degree. In contrast, thermal death due to raised temperature would take 10,000 times as much absorbed energy as radiation death. In fact, for some cells it is known, since the pioneer work of Dessauer (1, 2), that production of a single ion pair can cause lethal effect in the cell. In these cases, at least, lethal effect must be due to a chain of reactions.

Fourthly, as is generally known, a single inter-

action with ionizing radiation is able to make an inheritable change, or mutation, in the gene complement of cells. Radiation induced mutations are usually unfavorable, occasionally they can make cell metabolism more efficient. Thus radiation may have an important role in both destruction and evolution of life.

In order to comprehend at least a few of the complex phenomena involved in radiation effects on animals, it is useful to look at the explanation of the effects on unicellular organisms, and in order to understand these, one should study the physicochemical effects of radiation in inert chemical systems. The field is so large that all I can hope to give you is a list of some of the recent experimental approaches, then to describe, in a little more detail, some experimental findings of special interest to me. Excellent review articles by Bacq and by Curtis are available.

INTERACTION OF RADIATION WITH MATTER

Penetrating radiations either produce ionization directly in their passage through matter, as beta rays, alpha rays and protons, or they produce ionizing secondary particles as x-rays, gamma rays or neutrons. In the process of ionization, a negative electron is knocked out of an atom, leaving it positively charged. The negative electron attaches itself to a molecule, so that within 10^{-14} seconds a positive-negative ion pair is formed. The ions of the ion pair in liquid media often dissociate or interact with neutral molecules and form radicals or more stable chemical compounds. In addition, a number of atoms also

¹ The author's work was supported by the Atomic Energy Commission.

become 'excited' due to the passage of an ionizing ray, that is, one of the orbital electrons absorbs energy and is elevated to an excited state. The molecule in which the excited atom is located then might dissociate, emit a light quantum, interact with another molecule, or degrade the excitation energy by collisions with other molecules into vibrational and rotational energy. Dose may be defined, for the purposes of this discussion, as the energy absorbed in form of ionization and excitation per gram tissue. The radiochemical and radiobiological action of the ionizing radiation depends not only on dose, but on the geometrical distribution of ion pairs along each track. The number of ion pairs along a unit length of track is the 'specific ionization.' Among radiations available to experimentation, the specific ionization varies over a range of 100,000.

DIRECT ACTION

As to the mode of biological action of radiations, many early studies indicated that direct interaction of the ions with biological material occurs in some instances, causing splitting or fragmentation of large biological molecules. Classical example of such a process is the splitting of hemocyanin molecules as demonstrated by Svedberg and Brohult (3).

Experimentally, breakdown of macromolecules can be accomplished with different radiations: neutrons from the chain reacting pile, γ -rays, electrons, deuterons and alpha particles from the cyclotron, it can be performed on dry, biologically active molecules in the crystalline state, or in liquid suspensions. Some intriguing results to date include the following findings:

a) Breakdown of macromolecules by radiation sometimes occurs in fragments of well definable molecular weight (4).

b) In addition to breakdown, association of macromolecules can occur (5).

c) Quantitative study of the action of cyclotron-produced protons on crystalline enzymes leads to a novel method for determination of molecular weight (6).

d) When insulin was subjected to intense radiation with neutrons, a large part of the biological activity was retained in molecular fragments which had a variety of molecular weights (7).

The above instances indicate the potentialities of the 'molecular fragmentation' method in the breakdown study of biologically important molecules.

INDIRECT ACTION

In the second type of interaction of radiation with living matter, the primary ionization or excitation occurs at some distance from the molecules affected. As first clearly demonstrated by Dale (8), the indirect action occurs when the short-lived ions disappear, and give rise to radicals and intermediate chemical compounds in the liquid medium. The intermediates have much longer lifetimes than the ions themselves, and they can, in turn, chemically interact with protein molecules. In very dilute aqueous suspensions of enzyme molecules, the primary radiation effect is on water, and most of the effect is due to water decomposition products.

The decomposition of pure water, in its main features, is quite well understood, due to the work of Lind (9), Fricke (10), Weiss (11) and others (12, 13). We know that ionized water molecules almost instantly decompose into H and OH radicals, that these can readily interact, in the absence of oxygen, some hydrogen gas and hydrogen peroxide is formed. When oxygen is also present, dissolved in water, the radical HO_2 forms, which in turn enhances hydrogen peroxide formation. In the presence of organic matter, the formation of H_2O_2 is not observed, but the evolution of hydrogen is greater. When the water contains sulfhydryl enzymes with active SH groups, these are oxidized to form S-S bonds, presumably via interaction with the radicals.

Because the yield, lifetime, and interactions of intermediates depend on the chemical composition of the cell medium, one expects large variation of radiosensitivity due to environmental factors, such as temperature, pH, and composition of the medium. In contrast, the 'direct' effect is independent of these factors. Indeed, in living cells, striking environmental influences of radiosensitivity have been demonstrated.

Radiation sensitivity of an enzyme system depends on the composition of the aqueous medium. When substances are added to the medium that can compete for the radicals and other intermediates produced by radiation, due to the competition, the enzyme system can be partially protected from inactivation. An example, given by Barron *et al.* (14), is the protection from γ -rays of phosphoglyceraldehyde dehydrogenase with added glutathione. The same protective phenomenon was demonstrated in mammals by the brilliant work of Harvey Patt (15).

and his associates, who have recently shown that the amino acid cysteine, if administered to animals shortly before irradiation, increases their tolerance, so that twice the x-ray dosage is needed for lethal effect. Similar results have been achieved by Belgian workers with cyanide (16). At this meeting, workers from the Oakridge National Laboratory (17) presented data on an impressive array of organic substances which protect bacteria.

Indirect biological effects also depend on specific ionization (18). Spacing of ion pairs influences the yield of intermediates. In oxygen free water, for example, the dense ionization of alpha rays produces a high yield of H_2O_2 molecules. The yield of H_2O_2 remains small when sparsely ionizing x-rays are used. The enzyme phosphoglyceraldehyde dehydrogenase is partially protected from α -rays by catalase (19). Many biological systems are more affected by dense rather than by sparse ionization.

If some of the actual biological effects are caused by intermediate chemical compounds and not directly by ionization processes themselves, it should be feasible to produce similar effects with applied chemical compounds. Several types of radiation effects, notably chromosome breaks, mutations and carcinogenic effects (20, 21), have indeed been reproduced by a variety of chemicals. Typical agents that have similar effect to radiation are nitrogen mustards and peroxides.

Substances that contribute to formation of intermediates after exposure can increase the destructiveness of ionizing radiation. Thoday and Read (22) have shown that oxygen dissolved in the cell medium is known to increase radiation sensitivity. Lacassagne (23) demonstrated that baby rats are more resistant under anaerobic conditions than in the presence of oxygen, and Dowdy *et al* (24) showed that anoxic rats survive higher doses of radiation than normal ones.

Barron recognized the possibility that if radiation effects are due to chemical reactions, they should be, at least in part, chemically reversible. By the addition of glutathione he was able to reactivate some sulphydryl enzymes previously inactivated by radiation. A similar approach might possibly be of import in future therapy of radiation effects.

In the process of ionization or excitation, certain molecules receive a good deal more energy than is necessary for an ordinary chemical reaction. The new field of radiation chemistry con-

cerns itself with such unusual reactions. It is expected that ionization causes a number of irreversible reactions which would otherwise only occur at high temperatures and pressures.

Recently Garrison *et al* (25) have shown that carbon dioxide, dissolved in water and irradiated by alpha particles, produces some organic molecules, notably formic acid. Other investigators have for some time been studying a number of other interesting reactions. Mund (26) has shown polymerization of simple carbon compounds with occasional formation of cyclic molecules from straight chain substances. Dainton (27) has shown that certain low molecular weight monomers (e.g., acrylonitrile) in aqueous solution become polymerized into long chain polymers.

MECHANISM OF EFFECTS OF RADIATIONS AT THE CELLULAR LEVEL

In view of the great complexity of radiochemical reactions, many of which involve higher order reactions, it is surprising that the relationship of dose to certain types of biological effects is often relatively simple.

In many cases the dose-effect relationship has the properties of a monomolecular reaction. There are, however, cases which deviate from this simple relationship. The lethal effect in unicellular organisms may occur in the irradiated cells themselves, e.g., they fail to divide, and after the lapse of some time, they might undergo lysis. In another form of the lethal effect the formation of colonies is inhibited, but the irradiated cell lives on. Although it was known for some years that irradiation of the cell nucleus brings about lethal effect more effectively than irradiation of the cytoplasm (28), it seems likely that inhibition of cell division is due to genetic damage only in some species of cells and to extragenic destruction in others.

In association with Professor R. E. Zirkle of the University of Chicago, the Donner Laboratory group 2 years ago initiated a study of the mechanisms involved in the inhibition of yeast cells, *Saccharomyces cerevisiae*. French workers, Laterjet and Euphrussi (29), as well as Beam (30), have independently worked on the same problem and our respective results are not in disagreement. The approach was to test the relationship of dose to inhibition of cell division in haploid cells and compare the results of data obtained after irradiation of vegetative diploid colonies.

The morphological nutritional requirements

and growth rate of the haploid and diploid colonies were closely similar, and it was assumed that any differences in response to radiation effect would be due to the presence of paired genes and chromosomes in the diploid against the presence of one set in the haploid cells. It was further reasoned that if the radiation effect is most important in extragenic and extranuclear components of the cells, there should be no great difference in the radiation sensitivity of haploid and diploid cells. Detailed results of this investigation will be published elsewhere (31). We may, however, note here some of the conclusions. One great difference was found in the radiation sensitivity and in the dose affecting the relationship between haploid and diploid cells, the latter being about five times as resistant as the former. The relative shapes of the survival curves of cells in which cell division was not inhibited were compared, and the conclusions were mathematically in fair agreement with the following concepts:

a) Cell division is controlled in haploid cells from a number of mutually independent 'sites' (loci sensitive to radiation). Inactivation of any of these sites brings about inhibition of cell division. Inhibition can be the result of interactions initiated from a single ionization event. The probability of inhibition is proportional to dose, and the survival curve is a simple exponential function of dose.

b) In diploid cells, cell division is controlled from a number of mutually independent pairs of 'sites' which have similar functions to the sites in haploid cells. To inhibit cell division, it is necessary to inactivate both sites of an essential pair (allele). At least two ionization events are needed to accomplish this. The probability of inhibition of cell division is not proportional to the dose. The survival curve is of a sigmoid type.

c) Comparison of haploid and diploid survival curves can be made from the relative shape of the curves and the assumption that each 'site' is inactivated with the same probability. One concludes that in the haploid cells, there are about 16 sites essential to cell division, and in the diploid, 16 pairs of such sites.

Biochemical synthesis in cells is known to be under genetic control (32). It seems plausible to associate the sites sensitive to irradiation with independent biochemical processes controlled by genes.

The number of radiation sensitive sites is only an approximation which is expected to vary with environmental factors. In a medium very rich in various nutrients, there may be alternatives for each biochemical pathway so that the number of sensitive sites might be different. Yet it is of interest to note that this number is much smaller than the estimated total number of genes, and no proof is available as yet showing that single genes are affected. A mechanical disturbance, such as a chromosome break with loss of fragments during attempted cell division might be an acceptable concept of the mechanism involved.

From the above considerations, two important conclusions follow. In the first place, one would expect cells of higher ploidy of the same strain to show higher radiation resistance. The second consideration follows from the statistical nature of the distribution of radiation induced defects. If a colony of diploid cells is irradiated by a single dose, a number of the cells in which cell division is not inhibited will carry impaired genetic defects corresponding to inactivation of impaired radiation sensitive sites. Such defects should be hereditary and would make the cells less efficient in aspects of growth and metabolism, and more sensitive to radiation than normal diploid cells with no defects. Indeed, this was found to be the case experimentally. In certain experiments, as much as 50 per cent of the progeny of preirradiated diploid yeast cells showed an inheritable increase in radiosensitivity, accompanied in some cases by reduced vigor of growth and metabolism. Haploid cells surviving a preirradiation do not show these changes, which is a strong argument in favor of the recessive nature of such radiation induced effects.

The implication of these findings lies close at hand. By studying the biochemical nature of the abnormalities in the recessively defective diploid cells, one should get valuable data, not only concerning the components of radiation effects on cells, but also relating to essential steps in cell division. Since the general types of defects are limited to about 16 kinds (and combinations of these), it may be possible to proceed systematically. The further pursuit of this kind of study may also be of interest since it might uncover some clues concerning the nature of interaction between allelic gene pairs.

The experiments on yeast cells, carried out under a variety of environmental conditions, give clear indication that the mechanism in-

volved is indirect the ion pairs do not need to be produced at the 'site' of their action

The probability that an ion pair, through some intermediate process, can find an essential genetic component of the cell, is rather small, hence, many other ion pairs and interactions are produced elsewhere within the cell before the inhibition of cell division occurs. These, collectively, may be responsible in the yeast cells for diverse effects of radiation, delay in cell division, swelling, etc. In many species of cells they may even be responsible for the actual lethal effect.

When a large colony of diploid cells is irradiated, even with a dose much larger than the 50 per cent LD, one finds some cells which have received no genetic defect at all. This is due to the statistical spatial distribution of ionization. Such cells may play an important role in the 'recovery' phenomenon well known in radiobiology. When many generations of growth have passed between one irradiation and the next, most of the cells present in the preirradiated colony exhibit normal radiation resistance. This may be due to the fact that diploid cells left unaffected by radiation, and those which mutated back to normal, outgrow the ones with genetic defects.

It would be desirable to have detailed information on the mechanism of radiation effects on other microorganisms. Much work is being done in this field, unfortunately we do not as yet have sufficient information to indicate whether or not the process of inhibition of cell division is similar in each case.

RADIATION EFFECTS ON MAMMALS

There is a very long step between physiological simplicity of yeast cells and the complexity of mammals. Many experiments will have to be performed before the radiation effects are understood in the latter. However, there are certain similarities I wish to point out.

When a part of the body of a young animal is irradiated with a sublethal dose, one often finds a prolonged retardation of growth of that tissue lasting for several generations of cells. For example, an irradiated limb in a baby animal may remain stunted for a long period of time. Though there are many factors involved, e.g. radiation effects on vascular bed and connective tissue, some of the surviving irradiated cells have possibly unpaired genetic defects which slow the rate of growth and metabolic efficiency of each

cell. Histologically, regeneration in such tissues often follows a curious pattern. In the middle of a seemingly devastated area of impaired cells, a small island of normal young cells appears. These cells appear to originate from a single cell, possibly one that did not suffer any genetic damage from the irradiation. This phenomenon is observed in therapeutically irradiated tumor tissue as well. One might speculate on the frequency and importance of impaired genetic defects produced by radiation in the diploid germ cells of mammals. By reduction division these produce haploid gametes carrying lethal genetic defects, which in turn would give rise to recessive lethals in the offspring (32). The presence of such processes will have to be proven experimentally.

Radiation effects on the tissues of higher animals should not be directly compared to those of microorganisms. The functioning of each organ in the body depends on the functioning of other organs. When the total body is irradiated, one obtains not only direct radiation effects on the cells of each tissue, but indirect effects as well, due to changes in internal environment. The internal environment is chiefly modified by humoral agents. Investigations carried out with partial body irradiation of small animals have shown the validity of some fairly general rules.

a) There are important, remote effects on various organs when they are themselves shielded from radiation, but other parts of the body are irradiated. These effects probably originate from deficiencies in the blood composition or toxic substances carried by the blood. According to Hevesy (33), nucleic acid synthesis is diminished if a remote part of the body is irradiated. Kelly and Jones (34) amplified this finding by showing that selective irradiation of the liver with a radioactive colloid materially affects nucleic acid synthesis in tumors. Van Dyke and Huff (35) irradiated one member of a pair of parabiotic rats. Epilation of the hair extended not only to the irradiated animal, but also to its shielded twin. They have thus demonstrated that a toxic substance or a depletion of some essential blood constituent has transmitted the effect via the cross-circulation between the animals.

b) Animals survive a greater dose of partial body irradiation than of whole body irradiation. The data of Bond *et al* (36) show that partial irradiation of the abdomen increases the LD 50 in rats by a factor of 2. Similar recent informa-

tion was gained by Jacobson *et al* (37, 38) who have shown that shielding of the spleen alone increases the 50 per cent LD by a factor of 2 and that shielding of almost any part of the body (e g head) affords some protection against radiation effect. When one member of parabioc twins is irradiated, the lethal dose for that member is very significantly increased (35). All these results strengthen the assertion that in mammals, a significant fraction of acute radiation effect must be extragenic and mediated by the humoral agents.

Selective irradiation of a portion of the animal body is not easy to perform with x-rays. The Donner Laboratory group (39) is utilizing high energy deuteron ion beams which allow irradiation of a small deep-seated region of the body without materially affecting the overlying tissues. In one of the experiments, done in collaboration with the Institute of Experimental Biology (40), the anterior pituitary gland of rats was irradiated, and a study of the overall and differential effects on secretion of pituitary hormones is under way.

A few years ago attempts for therapy of the acute radiation syndrome seemed to be quite hopeless. With the realization that many of the

symptoms are due to humoral agents, we can now look forward with some confidence to the development of at least partial therapeutic measures. One should diligently continue the inquiry into the nature of blood constituents that are most affected by radiation, and further study the effects of partial body irradiation. There is already wide knowledge of the impairment of the blood clotting mechanism (41). In addition Rosenthal (42) recently reported opalescence in the blood serum of rabbits which showed high correlation with subsequent death of the animals due to radiation effects. The Donner Laboratory group (43) has identified the molecules causing opalescence as a group of abnormal lipoproteins. Very recently Jacobson *et al* (38) have demonstrated that lead-shielded spleens partially protect rats from lethal effects of radiation even if the circulation of the shielded spleen is clamped off during exposure to x-rays, and released soon after exposure. Further they showed that transplantation of normal baby rat spleen into the peritoneal cavity of whole body irradiated rats also gave significant protection. This 'therapeutic' influence seems to originate from humoral agents secreted from the spleen.

AMERICAN PHYSIOLOGICAL SOCIETY

*Symposium on Demand and Supply of Energy for Function**

Chairman JOHN O HUTCHENS

THERMODYNAMIC PRINCIPLES AS APPLIED TO THE ANALYSIS OF BIOLOGICAL SYSTEMS¹

JOHN Z HEARON

From the Department of Physiology, University of Chicago, Chicago, Illinois

AMONG the general purposes of this symposium is the discussion of the free energy (or work) requirements of certain biological processes and the examination of the relation between such requirements and the free energy made available by spontaneous, metabolic processes

It is the particular purpose of this paper, in addition to furnishing a brief thermodynamic background, to formulate the above stated problem, to make clear certain concepts encountered in such formulations, to discuss the form which the laws of thermodynamics must take when applied to the kind of system met with in biology and to acknowledge (with no pretense of here solving in detail) problems which arise from the inherent nature of biological systems and in the statement of the general problem posed in this symposium

It is clear that the above outlined objectives and the constraints of reasonable space are incompatible unless some other condition is imposed. It might then be anticipated that treatment here will be brief and include frequent reference to published and forthcoming work. Any attempt to avoid formal development is doomed from the start and would result in an unbearable clumsiness of expression. The attempt has been made, however, to include only such formalism as is demanded by reasonable standards of rigor and by the fact that physical intuition is no safe guide in all situations

1 SECOND LAW AND CRITERIA OF SPONTANEITY

It will be recalled that the First Law of Thermodynamics is a statement of the conservation

of energy in which recognition is taken of the equivalence of heat and work. The usual statement is

$$dE = dQ - dW \quad (1)$$

where dE is the increase in internal energy of the system, dQ the increment of heat absorbed by the system from the environment and dW is the increment of work done by the system on the environment. Sight should not be lost of the fact that dW is external work and is zero unless provisions are made for the system to perform work against external forces. The First Law places no limitations upon the transformation of energy from one form to another but demands only that energy be conserved.

On the other hand, the Second Law imposes a limitation upon the interconvertibility of energy. The statements of this limitation are many and familiar (1-3). They are all equivalent, as can be demonstrated (2, pp 127-9, 3, pp 31-35), to this statement: No process can occur the only result of which is the conversion into an equivalent amount of work of heat extracted from a source which is at uniform temperature throughout. This statement, based upon invariant human experience, completes the inductive stage of thermodynamics. The law is then stated in the form of an axiom and the methods of logic and mathematics are brought into play to develop the consequences, producing an assemblage of theorems or propositions. These comprise the well studied array of formulae, equations, etc., of thermodynamics which cover a vast range of physical situations and are of remarkable generality. This department, in some ways simplest of all, is the so-called pure branch of thermodynamics.

The usual point of departure in discussing the consequences of the Second Law is the statement

$$T dS \geq dQ \quad (2)$$

* April 30, 1951, Cleveland, Ohio

¹ The original investigations referred to in this paper were supported in part by a grant from the Dr. Wallace C. and Clara A. Abbott Memorial Fund of the University of Chicago

where dS is the change in entropy of the system and T is the absolute temperature at which the increment of heat dQ is absorbed. The equality sign in equation 2 holds for a reversible process, the inequality for a spontaneous or irreversible process. If the system is isolated such that $dQ = 0$, equation 2 becomes

$$dS \geq 0 \quad (3)$$

which states that the entropy of an isolated system can never decrease. If the process is reversible, the equality in equation 3 holds and the system suffers no change in entropy. It must be remembered that equation 3 applies to an isolated or adiabatic system for it is possible, with the aid of an external system, to decrease the entropy of a given system. The conditions under which equation 3 applies may be achieved by isolating the system in a manner such that its energy is fixed and it can do no work upon the environment. For example, if the system can perform only pressure-volume work (PV work) then equations 1 and 2 show

$$dS_{E,V} \geq 0 \quad (4)$$

thus the entropy at constant energy and volume can never decrease. The system can in principle always be so isolated by 'including the environment'. Thus the entropy of the system plus environment never decreases, as frequently stated—the entropy of the universe increases as a result of an irreversible process. By 'universe' is meant the system and that part of the outside world with which it may interact. A process which occurs under such conditions of isolation is plainly spontaneous in that it occurs of itself, i.e. with no external aid.

Now the conditions under which the entropy change may be used as a criterion of spontaneity are difficult to achieve and almost never dealt with in laboratory practice. The usual experimental conditions are constant temperature and pressure or, occasionally, constant enthalpy and pressure (e.g. in constant pressure, adiabatic calorimetry, $dQ = 0$). The most useful function will then be the (Gibbs) free energy, F , defined by

$$F = H - TS \quad (5)$$

where

$$H = E + PV \quad (6)$$

is the enthalpy or "heat content" and P and V the pressure and volume. If we write the work as

the sum of PV work and work of other kinds, then for a reversible process

$$dW_r = dW'_r + P dV \quad (7)$$

where dW'_r will include reversible electrical, length-tension, etc., work. It follows from equations 5, 6, 1 and 2 that for a reversible process at constant temperature and pressure,

$$dF_{T,P} = -dW'_r \quad (8)$$

It is a direct consequence of equation 2 and the fact that dE is the same for a reversible and irreversible change that

$$dW_r \geq dW \quad (9)$$

thus

$$dF_{T,P} \leq -dW' \quad (10)$$

Equation 10 applies to any process at constant T and P . If $dW' = 0$, e.g. if the system can perform only PV work, then $dF \leq 0$. If the system is allowed to do work on the environment (i.e. the environment does *not* perform work on the system) then dW' is positive or zero, and in this case too, $dF \leq 0$. Thus the free energy of a system, at constant T and P , which is permitted to do work on its environment can never increase. When the free energy reaches a minimum no further change (without work by an external agency), can occur for this would entail an increase in free energy. The system is then in stable equilibrium. Further, according to equation 10, as long as the free energy can decrease, useful (non PV) work can be performed and when equilibrium is reached no further work can be performed. All of this is well known. The point which is here stressed is that the derivation of equation 10 and the conclusions drawn from it are based squarely upon equation 2. We cannot insist that the entropy increase except in an isolated system. But for every statement about the entropy of an isolated system there is a corresponding statement about the free energy of the same system at constant T and P . In fact it can be shown (4), cf. SECTION 3, that the simplest manner in which to compute $dS_{E,V}$, equation 4, is by computing $dF_{T,P}$. Moreover it can similarly be shown (5, cf. 6 pp. 62–3) that the straightforward and simplest calculation of the entropy change at constant H and P (under which condition T changes as a result of the process) hinges upon the calculation or knowledge of $dF_{T,P}$. The 'simplicity' in these cases is due to the agreeable properties of the chemical potential.

In view of these last remarks and the role of the free energy change in the assessment of dissipation of energy in irreversible processes (SECTION 3) we now turn to a discussion of

2 FREE ENERGY CHANGE OF CHEMICAL REACTION AND TRANSPORT

For the usual² chemical system the free energy is completely specified when T , P and the number of moles of each chemical species are prescribed. This evidently requires that T and P be uniform throughout the system. Even when this condition is satisfied additional information is needed if the system is spatially distributed (4, pp 96-8). The statements in what follows immediately can be modified for spatially distributed, open systems with no essential change in principle. Denote by n_k the number of moles and by μ_k the partial molal free energy (or chemical potential) of the k th substance. The free energy is given by

$$F = n_1\mu_1 + n_2\mu_2 + \dots = \sum_k \mu_k n_k \quad (11)$$

The chemical potentials μ_k , will be taken as

$$\mu_k = \mu_k^0 + RT \ln C_k \quad (12)$$

where R is the molar gas constant, C_k the molar concentration and μ_k^0 the so-called standard chemical potential of the k th substance. The μ_k^0 are functions of T , P and the nature of the solvent. Equation 12 embodies all of the assumptions³ regarding perfect, dilute solutes. Consider the chemical reaction

in which, stoichiometrically, m_1 moles of A_1 , m_2 moles of A_2 etc react to give m_4 moles of A_4 , etc. If we adopt the convention that the m 's are assigned negative values for reactants and positive values for products then

$$dn_k = m_k dN \quad (13)$$

where N is the "degree of advancement of the reaction" (9) and dn_k the number of moles of substance k produced when the reaction proceeds by the amount dN . The composition of the system is describable in terms of the initial number of moles, n_k^0 , and the single parameter, N . With

² We must exclude strained elastic solids, systems in which surface energy is an appreciable part of the total, etc.

³ In particular equation 12 implies (4, p 93, 7, 8, p 189) that there is no heat or volume of dilution

no loss in generality we assume that initially $N = 0$, then

$$n_k = n_k^0 + m_k N \quad (14)$$

If F_2 and F_1 are the values of free energy in the final and initial states in which the concentrations are C_k and C_k^0 respectively, then it follows straightforwardly from equations 11, 12 and 14 that $F_2 - F_1 = \Delta F$ is given by

$$\Delta F = N[\Delta F^0 + RT \sum_k m_k \ln \frac{C_k^0}{C_k}] + \sum_k (n_k^0 + m_k N) RT \ln \frac{C_k}{C_k^0} \quad (15)$$

or

$$\Delta F = N[\Delta F^0 + RT \sum_k m_k \ln C_k] + \sum_k n_k^0 RT \ln \frac{C_k}{C_k^0} \quad (16)$$

Where ΔF^0 is the standard free energy change. In equation 15 the quantity in brackets gives the free energy change, per equivalent,⁴ at the initial concentration, the remaining terms give the free energy change of adjusting the final number of moles, $n_k^0 + m_k N$, from initial to final concentrations. Similar remarks apply to equation 16. In spite of complications which may arise in applying equation 15, or a modification of it, to biological systems a fortunate, simplifying condition is frequently met in practice (10). Evident from equation 15 is the fact that if some reactants are completely consumed so that the final number of moles is zero and if the concentrations of some reactants do not change and if, further, the concentrations of none of the products change, then the terms in equation 15 associated with the changes in concentration vanish (e.g., substances such as O_2 and CO_2 are under usual conditions present at constant concentration, products such as starch, glycogen and fat are present at constant, saturated, concentration, and added substrates such as acetate, ethanol, etc are completely consumed). It can be shown (11) that rather restrictive numerical limitations can be placed upon the terms, in equations 15 and 16, associated with concentration changes and numerous special cases can be discussed.

If many reactions are proceeding, as is usually the case in practice, then the extension of the above discussion is as follows. Let N_j be the degree of advancement of the j th reaction and

⁴ Clearly, from equation 14, $N = (n_k - n_k^0)/m_k$ is the number of equivalents of any reactant converted or of any product formed.

m_{kj} the stoichiometric coefficient of substance k in the j th reaction Then

$$\left. \begin{aligned} dn_k &= \sum_j m_{kj} dN_j \\ n_k &= n_k^0 + \sum_j m_{kj} N_j \end{aligned} \right\} \quad (17)$$

For the total change in free energy one then obtains a sum of expressions, each of which is similar to equation 15 or 16 This causes no difficulty However, when, and this is the rule in biological systems, certain substances participate simultaneously in several reactions some special discussion (see SECTION 4) is needed for the calculation of 'efficiency'

Finally it follows (12) from equations 11, 12, 13 that the time rate of change of the free energy is given by

$$\frac{dF}{dt} = \sum_k \mu_k m_k \frac{dN}{dt} \quad (18)$$

where dN/dt is simply related to the usual chemical kinetic expression for the reaction rate If consecutive reactions, branched or coupled, are involved the summation is extended over all steps involved (12)

Consider a system consisting of two uniform phases Let n_1^0 and n_2^0 be the initial number of moles of a given solute and C_1^0 and C_2^0 the initial concentrations in the phases If n moles are transferred from 1 to 2, the free energy change is

$$\Delta F = nRT \ln \frac{C_2^0}{C_1^0} + (n_1^0 - n) RT \ln \frac{C_1}{C_1^0} + (n_2^0 + n) RT \ln \frac{C_2}{C_2^0} \quad (19)$$

where C_1 and C_2 are the final concentrations and it has been assumed that the standard chemical potential is the same in the two phases If several solutes are transferred the total ΔF is obtained by summing expressions such as equation 19 Strictly speaking, when ions are transferred, in addition to substituting activities for concentrations in equation 19 there should be added a term $nz\mathcal{F}\Delta\mathcal{E}$ where z is the valence, \mathcal{F} the Faraday and $\Delta\mathcal{E}$ the electrostatic potential difference between the phases In summing over all species involved, however, such electrical terms must cancel (8, 13)

If the system under investigation is not spatially uniform then the treatment in this section requires modification In the first place the free energy is no longer given by equation 11 for the values of the μ_k depend upon the point in the

system at which they are evaluated The total free energy is now given (4) by

$$F = \int_v \sum_k \mu_k C_k dV \quad (20)$$

when the μ_k and C_k are functions of the spatial coordinates and the integral is extended over the volume of the entire system If there are gradients in concentration there will in general be flow of matter, although this is not necessarily true of every solute In any event the μ_k and C_k are determined at every point by the rates of diffusion, of chemical reaction and of flow of matter across the surface of the system The value of F may not be changing with time, as is the case (4) in the steady state, but the value of equation 20 is still determined by the rates at which processes occur within the system Here we see an important example of the interplay of 'thermodynamics proper' and rates The time rate of change of F for a spatially distributed, open system is simple to obtain formally, often difficult to apply It can be shown (4) that

$$\begin{aligned} \frac{dF}{dt} &= \int_v \left\{ J_x \frac{\partial \mu}{\partial x} + J_y \frac{\partial \mu}{\partial y} + J_z \frac{\partial \mu}{\partial z} \right\} dV \\ &+ \int_v \mu q dV + \int_s J_s \mu ds \end{aligned} \quad (21)$$

where J_x is the flow, per unit area, per unit time, in the x -direction and similarly for J_y and J_z , q is the rate of production, per unit volume, J_s is the flow in the direction perpendicular to the surface, s , of the system Equation 21 has been written for one solute such expressions for all solutes are summed in the general case The first integral gives the contribution from the flow or transport of substances in the system due to the fact that gradients exist, the second integral is the contribution due to chemical reaction and when q is expressed according to chemical kinetics the integrand is a sum similar to equation 18, the last integral is the contribution due to the flow of matter, across the surface, into the system An important special case is the evaluation of the first integral in equation 21 for the case of a region (cell) in which concentrations are uniform, separated by a barrier (membrane) from another region (environment or extracellular space) which is likewise uniform There will be no gradients except the 'concentration drop' across the membrane We may assign the membrane a finite thickness, attribute to it the properties of a

bulk phase⁵, or take it in the limit as infinitesimal, or plead complete ignorance of the dimensions and properties of the barrier. The appropriate expression can be shown (4) to be

$$\left(\frac{dF}{dt}\right)_{diff} = A J R T \ln \frac{C_0}{C_i} \quad (22)$$

where A is the area of the membrane, J the flow (per unit area and time) out of the cell and C_0 and C_i are the concentrations outside and inside the cell respectively. The product AJ is the total flow (moles/time) out of the cell and (13) may be evaluated empirically without reference to the formal law of flow across the membrane. Equation 22 is for a single solute and embodies the assumptions discussed for equation 19. It should be mentioned that if concentrations are not uniform within the cell then additional terms, frequently of the same order of magnitude as equation 22 are contributed. The use of equation 22 may then be a fairly rough approximation but the error is not easily evaluated.⁶

3 FREE ENERGY, DISSIPATION OF ENERGY AND AVAILABLE WORK

According to the Second Law, the entropy, (unlike energy, volume, etc.), is not conserved when irreversible processes take place. From what has been said in SECTION 1, the entropy gain of a system is not equal and opposite to the entropy loss of the environment unless the process is reversible. If the process is irreversible, we are assured by the Second Law that the entropy of the system plus environment increases. Irreversible processes thus result in the creation of entropy. This is in essence the basis of the equality statement of the Second Law (9, 6, 17, 4). It may thus be stated that

$$TdS = dQ + dS^* \quad (23)$$

where dQ^* is the so-called uncompensated heat (9, 17). Equation 23 in conjunction with the inequality equation 2 shows that

$$dQ^* \geq 0 \quad (24)$$

⁵ This will lead to the usual permeability expressions (14-16)

⁶ To make the comparison between contributions from gradients inside and from the concentration difference across the membrane one must assign a permeability coefficient, a diffusion coefficient and dimensions of the cell. The results clearly depend upon these choices

Further,

$$dS = dS_r + dS^* \quad (25)$$

where dS_r is the entropy reversibly communicated to the system from the environment and dS^* is the entropy produced by irreversible processes which occur in the system, and is given by

$$T dS^* = dQ^* \geq 0 \quad (26)$$

The total entropy of a system does not necessarily increase but the irreversible production of entropy is positive or zero.

If one considers a system at constant energy and volume the entropy change for such a system must correspond to the irreversible production of entropy. For a process which can perform only PV work it can be shown (4) that

$$dS_{E,V} = -\frac{dF_{T,P}}{T} = dS^* \geq 0 \quad (27)$$

or for a finite change

$$\Delta S^* = -\frac{\Delta F_{T,P}}{T} \quad (28)$$

The physical significance of the irreversible production may be stated as follows. It can be shown that $T dS^*$, or $T \Delta S^*$ for a finite change, represents the dissipation or 'degradation' of energy which accompanies an irreversible process, i.e., this quantity represents the amount of energy rendered unavailable for useful work as a result of irreversibility. It is clear then that the irreversible production of entropy represents, in the above sense, the waste or inefficiency of the process in question, a matter with which accompanying papers (10, 13) are concerned. From equations 1, 23 and 26 it follows that

$$dE - T dS = -T dS^* - dW \quad (29)$$

Since, cf. discussion in (17) dE and dS depend only upon the initial and final states, the quantity $T dS^* + dW$ has a set value. If $T dS^*$ decreases dW increases correspondingly. Equations 1, 23 and 26 likewise imply that

$$dW = dW_r - T dS^* \quad (30)$$

which shows $T dS^*$ to be an amount of work which could have been performed had the process been reversible or the difference between the maximum possible work, dW_r , and the actual work, dW , in the irreversible process.

It can be shown (5) that for a process which can perform non PV work, that

$$dS_{E,V} = dS^* = -\frac{dF_{T,P} + dW'}{T} \geq 0 \quad (31)$$

from which

$$dW' = -dF_{T,P} - T dS^* \quad (32)$$

Equation 32 furnishes the equality statement corresponding to equation 10. It also states in view of equation 8, that the useful (non PV) work is the maximum or reversible work minus the energy dissipated.

It is difficult to exaggerate the simplicity of equations 27 and 31 and their derivations (4, 5) when comparison is made to the general formulation of the irreversible production of entropy (18) or the detailed derivation for special cases (6, 19) to which these results apply. We are in a position to write down at once the rate of dissipation of energy

$$T \frac{dS^*}{dt} = - \frac{dF}{dt} \quad (33)$$

for diffusion⁷ or chemical reaction by substituting equation 22 or 18 respectively into equation 33 and correspondingly for the cases of finite changes. It is easily shown (4) directly from the simple laws of diffusion that the rate of dissipation due to diffusion is the rate of work done against the forces of resistance to flow.

It is sometimes stated and often implied (e.g. 20-22) that the free energy dissipated in irreversible processes or the free energy not 'harnessed' or the energy wasted appears as heat. It is clear from the foregoing that this is not correct. The actual heat is related to the energy dissipated by equation 23. For a spontaneous chemical reaction the dissipation is numerically equal to the free energy change. In the special case of constant temperature and pressure when $\Delta S = 0$ then the dissipation is given by the heat evolved, viz., $-\Delta H$, which further implies that $\Delta F = \Delta H$ which is known not to be true in general. In the case of diffusion the dissipation is again numerically equal to the free energy change. If the solute is perfect² there is no heat change.

It is not legitimate to regard heat evolved as 'waste energy' nor does dissipated energy necessarily appear as heat.

4. CALCULATION OF EFFICIENCY

Consider an overall process which is spontaneous and which proceeds with a free energy change ΔF . Let it be capable formally of representation as the 'sum' of two component processes

⁷ In general the dissipation due to diffusion is given by the first integral in equation 21 preceded by a minus sign.

with associated free energy changes ΔF_1 and ΔF_2 . Then, since free energies are additive

$$\Delta F_1 + \Delta F_2 = \Delta F \quad (34)$$

Assume now for definiteness that ΔF_1 is positive and ΔF_2 negative. It will then be said that the second process 'drives' the first, and further, that the free energy 'available' from the second process is $-\Delta F_2$ and that 'used' in the first is ΔF_1 . The ratio

$$X = \frac{\Delta F_1}{-\Delta F_2} \quad (35)$$

is called the 'efficiency', i.e., the efficiency in the overall or 'coupled' process of the utilization of free energy made available by a spontaneous process in driving a non-spontaneous process. This quantity, which we will refer to hereafter as simply the efficiency, is also called the 'machine efficiency' (20, 10) and, more properly, the 'thermodynamic efficiency' (23).

The calculation and interpretation of efficiency as defined above requires at most what may be an inordinate amount of knowledge about the process and system and at least great care and thorough qualification in stating what is meant. Only in the simplest cases is it possible to unambiguously identify the quantities in equation 35 and assign them the meanings discussed above. In the remainder of this section the various factors and difficulties involved in the calculation of efficiency will be discussed. First, however, some remarks on the definition given in equation 35 will be made. The 'machine efficiency' was first discussed (20) in connection with the problem of whether or not organisms operate within the Second Law. It is easily shown from equations 34 and 35 that an efficiency of more than 100 per cent ($X > 1$) implies that ΔF is positive. It is well known that the effect of 'coupling' of processes is one of conservation of free energy. This is implicit in the definition of X , since⁸

$$X = 1 - \frac{\Delta F}{\Delta F_2} \quad (36)$$

Thus the smaller the loss in free energy, ΔF , the greater the efficiency. The term 'machine efficiency' is somewhat misleading since in many cases no external work is involved (e.g., expenditure of free energy in maintaining concentration gradients, chemical synthesis, etc.). The

⁸ This equation shows that, since ΔF_2 is negative, if ΔF is positive X exceeds unity.

use of this term for X as defined above may be clarified as follows. If the non-spontaneous component process is to occur alone this is possible (equation 8) only if some external agency does work in amount at least ΔF_1 upon the system. When the spontaneous component process occurs it is possible for the system to perform work in amount $-\Delta F_2$ upon some external agency. The efficiency is the ratio of these theoretical works, although in the actual coupled process it may be that no external work is performed. Finally, it can be shown that, in terms of the concepts discussed in SECTION 3, X is a measure of energy dissipated. From equations 27 and 36 it follows that

$$X = 1 - \frac{T\Delta S^*}{-\Delta F_2} \quad (37)$$

which states that the efficiency is unity minus the fraction of the (available) energy which is dissipated.

a) **Component processes** For the simple process

assume that conditions are such that

There is no question here that the component processes are those shown. In more complicated cases, however, (10) the overall process may be partitioned into component processes in several ways. Each partition leads to a different ratio of free energies and hence a different efficiency. The choice of component processes is usually clear from known pathways of intermediary metabolism. These problems are discussed elsewhere (10).

b) **Assignment of ΔF to a given reaction** A problem closely related to the one above is the following. The substance A is converted simultaneously to substances B and C

The calculation of the total free energy change is simple by the method already discussed (SECTION 2). We wish however to calculate the free energy change due *only* to the conversion of A to B . The concentration of A at any stage of the reaction is determined by how much A has been converted over *both* paths. The increment of free energy due to converting a small amount of A to B will then depend upon the amount of A

which has been converted over both paths. Clearly the quantity which we wish to compute depends upon the relative *rates* of the two reactions. If we define $f_1(t)$ and $f_2(t)$ as the number of moles of A which have at time t been converted to B and C respectively then it can be shown (11) that

$$\Delta F(A \rightarrow B) = \int_0^t \left\{ \Delta F^0 + RT \ln \frac{[B]}{[A]} \right\} \frac{\partial f_1}{\partial t} dt \quad (38)$$

is the desired quantity where $[B]$ and $[A]$ are the concentrations of B and A at any time. If n_A^0 and n_B^0 are the initial number of moles of A and B , equation 38 gives

$$\begin{aligned} \Delta F(A \rightarrow B) = & f_1 \left(\Delta F^0 + RT \ln \frac{[B]}{[A]} \right) \\ & + n_B^0 RT \ln \frac{[B]}{[B]_0} + n_A^0 RT \ln \frac{[A]}{[A]_0} \quad (39) \\ & + RT \int_0^t \frac{n_A^0 df_2 + f_2 df_1 - f_1 df_2}{n_A^0 - f_1 - f_2} \end{aligned}$$

The terms in equation 39, except the integral, are identical with the terms obtained when equation 16 is applied to the reaction in question. It can be shown that if the functions f_1 and f_2 are proportional, the last two terms in equation 39 give

$$\frac{f_1}{f_1 + f_2} n_A^0 RT \ln \frac{[A]}{[A]_0}$$

Thus the usual term in equation 16 contributed by the change in concentration in A is multiplied by the fractional amount of A converted to B . The problem can in principle be solved whenever the rates are specified whether they are empirically determined or otherwise known. In general such simple results as the above cannot be expected. This problem, illustrated by the very simple example above, is a prominent feature of the calculation of 'efficiency of synthesis' in which, for example, a substrate is simultaneously oxidized and assimilated.

c) **Available free energy** Perhaps the most vexing problem to be encountered in the calculation of efficiencies is that of deciding the amount of free energy 'available' for driving a given process. At least account must be taken of the resting, non nutrient or maintenance level of metabolism. If the available free energy is taken as that available from spontaneous processes above and beyond the maintenance level (10) it is then assumed that the cost of maintenance is not altered by the activity or synthesis in

question. Certainly circumstances can often be achieved wherein the 'correction' for resting or non-nutrient metabolism is negligible (10). But, in principle, one must entertain the idea that the cost of maintenance is not invariant under imposed conditions of activity. While, in the light of present knowledge, it cannot be asserted that activity and resting metabolism are even qualitatively the same it is probable that they are not utterly independent. As discussed elsewhere (12) it can be shown that various processes subserved by common energy-rich intermediates compete for such compounds. Thus the enhancement of a given process can suppress others with which it competes and conversely. If maintenance processes are not 100 per cent efficient, and this must be granted, then it is possible to divert energy from maintenance pathways without actually impairing maintenance.

The real problem here is that of identifying what may be called 'unavoidable waste'. We know that for spontaneous processes, processes proceeding at a finite rate, there must be dissipation. But what now is unavoidable waste?

Consider for example that among the processes competing for energy-rich intermediates there occurs wasteful splitting. It is known that such occurs and is even catalyzed by specific enzymes. Now the cell makes best use of available energy when the useful processes compete most successfully with wasteful splitting. This is governed by relative rates and those processes which are among the most successful competitors are most efficient. If wasteful splitting occurs this is just the type of information we wish to have reflected in an efficiency calculation. This is bad management on the part of the cell.

On the other hand consider the following situation. In computing the free energy of spontaneous processes if the calculation is made for the concentrations existing in the medium it is then assumed that a given amount of free energy is available. It is known that in general, but not necessarily (14), the concentration of a consumed substance is *lower* in the cell than in the medium. Calculation at the cellular concentration yields a different free energy. Moreover (equations 21 and 22) the difference corresponds to dissipation in the diffusion field. In general we would insist that this free energy is wasted insofar as syntheses are concerned. This is poor architecture on the part of the cell, open, non-uniform systems are naturally inefficient, this is unavoidable waste

consequent upon the structured nature of the system. But all of this is true if we are interested in a given synthesis and nothing else. It has been shown (4, 14) that as a result of the metabolism of substrates, non-metabolized solutes can be maintained at a higher concentration inside the cell than in the medium. More significantly, the cost of this maintenance is derived from free energy of the diffusion field of metabolized solutes. We cannot then regard the free energy of diffusion as wasted to the *total* economy of the cell. Conversely if the total free energy derived from metabolized solutes be regarded as available for maintaining concentration differences, the computed efficiency of this maintenance is quite low and under the circumstances discussed (4, 14) it is known that it is the free energy of diffusion alone which is responsible for this maintenance. The rates of free energy change due to diffusion and reaction are (equation 21) inseparably linked and assignment of free energy available for separate processes is often difficult.

It has also been shown (14) that soluble catalysts will distribute in a definite manner in the diffusion field of the cell. Often this distribution is such that the rates of catalyzed reactions are different (either greater or less) than would be the case if the same number of moles of reactant and catalyst were placed in a closed uniform system of equal volume. Such distributions are maintained by the diffusion free energy and, in addition to being regulatory devices, contribute to the cost of maintenance as certainly as do more obvious maintenances of structural integrity. An important feature is that such distributions and hence the cost of maintenance are shifted when new conditions are imposed upon the cell. It is a direct consequence of the general laws of diffusion and kinetics (14) that the rate at which a given process occurs is dependent upon the rates of other, chemically *independent*, reactions. The efficiency of a given synthesis will then be different when other syntheses are occurring.

Further examples cannot be discussed here. It should be clear from the foregoing that although efficiency calculations are based upon classical thermodynamics, often certain extra-thermodynamic information is required. In particular, rates, nature and concentration of intermediates and 'geometry' or structure play a major role in determining how well the cell can dispose of available energy.

FACTORS IN NERVE FUNCTIONING

ABRAHAM M. SHANES

From the National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Maryland

RECENT developments emphasize a close relation between nerve activity and ion movement. Hodgkin and his associates have presented the evidence in favor of their view that spike production is related to sodium entry, this is believed to be followed closely by the known exit of potassium (1-4). Keynes (5, 6) has obtained direct analytical data for sodium influx as well as for the previously established potassium escape. As recognized by these investigators, the data are either highly indirect and dependent on a number of assumptions or seriously dissociated in time from the bioelectrical events assumed to be involved.

Earlier studies (7-12) have led to the conclusion that slow changes in the polarization of both frog and crab nerve, under a large variety of conditions, are caused primarily by alterations in the potassium concentration at the fiber surface which result from the release and active uptake of potassium. If this were substantiated one would have at hand the opportunity to study and to correlate electrical phenomena simultaneously with ionic transfer and thereby to evaluate concisely the factors governing the kinetics and energetics of the system.

The purposes of this report are a) to describe briefly recent results of the study of potassium and sodium transfer in relation to the earlier bioelectrical observations, b) to provide a more precise approach to the kinetics of ionic and electrical phenomena for comparison with available data, and c) to employ these principles for a preliminary survey of the energetics of the resting and active state. Full details will be given elsewhere.

RESULTS

Anoxia BIOELECTRICAL OBSERVATIONS Oxygen lack causes progressive depolarization which is slowed by glucose but accentuated by iodoacetate poisoning whether glucose is present or not (7, 11-15). Return to oxygen leads to repolarization, usually with overshooting (7, 11, 15, 16), in glucose the amplitude of repolarization is less (11, 12).

ANALYTICAL DATA Almost simultaneously evidence was reported for frog and crab nerve (17, 18) that anoxia causes potassium release, thereby refuting earlier claims to the contrary (19, 20), reabsorption was noted during the period of oxidative recovery. Glucose was found to reduce the ionic shifts in invertebrate nerve (18).

More details have now been obtained for frog nerve. Table 1 confirms the finding by Fenn and Gerschman that anoxia causes potassium release. In addition it demonstrates that glucose retards this loss and that iodoacetate poisoning inhibits the sugar effect. Because of its importance for the theoretical development later, mention must be made of our failure to confirm the conclusion by Fenn and Gerschman (17) that potassium release is not a continuous process throughout anoxia. Our experiments, now numbering in the hundreds, involve repeated analyses of the media from the same nerves as well as of the nerves themselves, none has failed to demonstrate a continuing loss of potassium.

Table 2 illustrates that removal of the external sheath improves potassium escape during anoxia only slightly but is essential for a demonstration of potassium uptake during a single hour of recovery. The unimportance of the sheath for the anoxic release indicates that another boundary, such as the individual fiber membranes, may be limiting potassium movement under these conditions. When potassium shifts are rapid, as may be the case during recovery or during stimulation, the epineurium would be expected to be the limiting factor.

Table 3 summarizes sodium and potassium data obtained by analyses of the nerves immediately following anoxia. In general, the escape of potassium is accompanied by an uptake of sodium, the latter being greater as described for stimulation (6). The protective action of glucose extends to sodium as well as to potassium. Within the error of our measurements of dry and wet weights, water movement usually was not significant.

Veratrine and Cocaine BIOELECTRICAL OBSERVATIONS These alkaloids have opposite effects

on the rate of anoxic depolarization, the anesthetic decreases, the 'unstabilizer' increases it (9, 11, 12, 21). Many other compounds (22), including procaine and antihistamines (12, 21), duplicate the action of cocaine and may be called 'stabilizers', at physiological concentrations, such as employed here, no respiratory effects are demonstrable (23). Veratrine, however, increases the respiratory rate (24). The antagonism be-

¹ Potassium absorbed from medium

tween veratrine and cocaine is shown particularly clearly by the prevention of the depolarizing action of higher concentrations of the alkaloid mixture by low concentrations of the stabilizer (12).

ANALYTICAL DATA Figure 1A illustrates a) the increased escape of potassium in veratrine concentrations which cause depolarization and b) its complete prevention by cocaine in concentrations which prevent veratrine depolarization. Figure 1B demonstrates the ability of cocaine to

block veratrine action even after the alkaloid mixture has acted for some time, the cessation of potassium release in this case is followed by a significant absorption. Table 4 provides typical data showing the increased release of potassium during anoxia in veratrine concentrations too low to cause either depolarization or potassium release in oxygen. Table 5 shows the behavior of both sodium and potassium. As in anoxia, sodium entry usually exceeds potassium exit in veratrine, both are prevented by cocaine. The anesthetic also reduces sodium and potassium transfer during anoxia, but its effectiveness is substantially less than in veratrine. In all of these cases water shifts were not significantly greater than the experimental error of the weight determinations used for their measurement.

Stimulation BIOELECTRICAL OBSERVATIONS The after-potentials of crab nerve are particularly suited for correlation with other less accessible characteristics because of their typical slowness. Under special conditions the well-known depolarization during a tetanus (14) is followed by recovery leading to an overshooting of polarization level which apparently represents a positive after-potential (11). The relation of the depolarization to the negative after-potential is shown by its increase with veratrine, the amplitude of the repolarization is correspondingly greater (11, 25).

ANALYTICAL DATA These were obtained as in most of the previous experiments by analyses of small volumes of media recirculated past the nerves and collected at regular intervals, the perfusion units employed permitted concomitant observation of the spikes with stimulation. It has been found that in addition to the potassium escape long known to accompany activity, potassium reabsorption occurs during recovery, moreover, these shifts, like the corresponding electrical changes, are accentuated by veratrine (25).

In frog nerve potassium release also results from stimulation (26). The earlier work has been considered questionable because rather extreme conditions of stimulation were necessary. Table 6 illustrates the considerable increase in the potassium released per impulse when the external sheath of bullfrog nerve is removed. Milder stimulation, practicable in the absence of the sheath, gives about the same loss per impulse as a more rigorous tetanus. As in crab nerve, low veratrine concentrations increase potassium es-

cape during tetani Potassium uptake following stimulation has not been seen in this tissue, however this may have been obscured by the potassium loss which occurs from *R. catesbiana* nerve, whether sheathed or desheathed, even when at rest in oxygen

Studies restricted to desheathed fibers must be regarded as tentative pending the evaluation of the significance of the considerable swelling they

measurements on the assumption that accumulation of potassium in the extracellular spaces, such as would occur in the usual moist chamber situation if potassium did actually leak out, could be computed from the known depolarizing action of excess potassium when applied by way of the external medium Although the predictability of potassium behavior is now in favor of the original hypothesis, our more recent finding that sodium

undergo in 3 to 4 hours their weight increase approaches a maximum of 30 per cent relative to the initial weight with sheath, and of 40 per cent relative to that without sheath Sodium is also gained in amounts equivalent to the entry of isotonic saline These effects may be extrafibrillar for a) the potassium content relative to the dry weight is little changed, b) the spike heights and the ability to withstand repetitive activity are not affected significantly, and c) the improved absorption of potassium following anoxia is hardly attributable to damage Fortunately, invertebrate and intact vertebrate nerve provide a check on the results with desheathed fibers

In view of the data which have been presented, the conclusion appears unavoidable that potassium shifts—and corresponding exchanges by sodium where these have been followed—are intimately correlated both in direction and time with the after-potentials and the changes in resting potential

THEORY AND RELATED DATA

Sodium vs Potassium BIOELECTRICAL OBSERVATIONS The observed movements of potassium were predicted from the earlier electrical

potassium accumulation or from its prevention or decrease. In this connection Feng's observations on the failure of conduction during anoxia and iodoacetate treatment and the utilization of lactate during iodoacetate poisoning only when oxygen is present, parallel perfectly later findings on the state of polarization (15). This is in accord with the very early conclusion that the polarization level is an important element in conduction. The recent experiments of Lorente de N6 (16) lend further support to this view as well as to the postulate that conduction failure, where depolarization is known to occur, is an index of such

moves in the opposite direction—particularly in the light of Ussing's suggestion (27) that sodium extrusion is the primary process responsible for frog skin potentials—raises the question as to which ion, if either, is immediately linked with metabolism and concerned with the electrical changes.

Several observations in the literature, and some which we have recently made, seem to provide definitive answers. With regard to anoxic failure, Feng and Gerard (28) reported that the mere washing of anoxic frog nerve with oxygen-free solution caused partial recovery. Feng (29) reported two observations to the effect that conduction failure occurred more quickly when nerves exposed to iodoacetate were mounted in a moist chamber than when they were kept in a large volume of the same iodoacetate Ringer. Similar observations for anoxia have recently been reported for frog nerve (30). These are obviously results such as would follow from

depolarization. His demonstration that an anodal current restores conduction and repolarizes in the continued presence of experimental agents which have been demonstrated to cause potassium release, may now be taken as evidence for the integrity of the semipermeable properties of

Fig 2 TEMPORAL CHARACTERISTICS of functional changes of a squid axon, only partly cleaned, a) in nitrogen gas, b) upon washing with nitrogenated sea water ■, c) upon return to oxygen gas, and d) upon washing with oxygenated sea water □ Spike height and latency (including conduction time) in inches of oscilloscope deflection

and conduction by washing and anodal currents appears irreconcilable with Ussing's proposal that failure of sodium extrusion leads to depolarization, conversely, the accumulation of excess extracellular potassium is in simple accord with known facts and provides a consistent explanation for the observations

ANALYTICAL DATA The possibility of distinguishing between a mechanism concerned with potassium uptake rather than with sodium extrusion is afforded by observations on the effects of a low sodium level in the medium on ion transfer With the sodium concentration reduced to that of potassium, the sensitivity attained for detection of sodium shifts is almost equal to that for potassium, moreover, analyses can be carried

the fiber membranes and for the transport back into the fibers by the current of the potassium which had leaked into the surrounding space
The effects of washing have been examined in a system where barriers to electrolyte transfer are close to a minimum—the nerves and giant axons of the squid Figure 2 illustrates the dramatic effects noted for the action potential of a partially cleaned giant axon Washing with oxygen-free solution, after failure in nitrogen gas, restored the spike height and normal conduction velocity practically instantaneously and this could be repeated many times, return to oxygen from nitrogen gas, on the other hand, required 2½ to 3 minutes for the spike to first appear and longer still for it to approach normal amplitude It is significant that the changes in spike height and conduction velocity in nitrogen are such as to be expected from an excess of potassium (31, 32)
The restoration of both the resting potential

out for both sodium and potassium on the same medium samples
Table 7 demonstrates the behavior of nerves first in oxygen then in nitrogen after one-hour equilibration in Ringer or in a low sodium Ringer The potassium losses during anoxia are about the same in either Ringer—perhaps somewhat less in the low sodium Ringer if allowance is made for the initial tendency of potassium loss in this solution to be maintained at a somewhat higher level than in the control Sodium liberation, which is chiefly or exclusively from the extracellular spaces (33), occurs at a continually decreasing rate in accord with the exponential function observed in controls and with no indication of an additional decrease when nitrogen is introduced Experiments with longer equilibration periods in regular and low sodium Ringer were also tried but were unsatisfactory because potassium losses in oxygen were very high in the latter solution, respiratory inhibition probably

is involved (34) The experimental results therefore demonstrate that potassium release in nitrogen is not contingent upon sodium entry, from this it may be concluded that potassium exit is the primary consequence of metabolic inhibition and sodium influx is secondary In the absence of analytical data, the same relationships may be assumed to apply to potassium reabsorption during recovery

KINETICS THE RESTING STATE From the available facts we may conclude that a nerve in apparent equilibrium with its environment with respect to potassium and sodium achieves this by the absorption of potassium at a rate exactly equal to the tendency of this ion to escape Evidence has been presented (8, 10, 11) for regarding the enzymatic process of uptake to be directly related to the potassium concentration at the fiber surface, K_s , as a first approximation the relation may be considered linear The rate of escape would be governed by physical characteristics of the system such as permeability and concentration differences The rate of increase of the intracellular concentration, K_i , due to metabolism is therefore

$$\frac{dK_i}{dt} = kK_s, \quad (1)$$

and the rate of decrease because of physical factors is

$$\frac{dK_i}{dt} = -P_1(K_i - K_s), \quad (2)$$

in the steady state these are equal and opposite, hence, since $K_s \ll K_i$,

$$\frac{k}{P_1} = \frac{K_i}{K_s} \quad (3)$$

The rate constant, k , for metabolism should therefore be greater than the permeability constant P_1 (which also includes geometrical factors) by the ratio of intracellular to extracellular potassium concentrations On the basis of the potassium-potential relationship, an approximate indication of the relative magnitudes of these constants may be obtained from the maximal rates of post-anoxic repolarization and of anoxic depolarization These are of the order of 100 1 in frog nerve, which is roughly the potassium ratio in this tissue (see below)

Equation 3 is of importance in indicating that alterations in metabolism as well as of the permeability will change the equilibrium If valid it provides one means of evaluating permeability

changes which may be induced by experimental agents like cocaine that leave respiration unaltered This is presently under investigation

ANOXIA The washing and anodal repolarization experiments previously mentioned indicate that structural characteristics related to the functional activity of nerve remain intact for long periods during anoxia Glycolysis serves as a source of energy, but only to a limited extent, according to Feng (35) lactic acid production accounts for the residual energy release of frog nerve during anoxia The combination of anoxia and iodoacetate therefore may be regarded to achieve practically complete cessation of the metabolic machinery for potassium uptake Let us assume that structural integrity is still maintained¹ Figure 3 gives the simplified model of a nerve and the differential equations derived there-

Fig 3 SIMPLIFIED MODEL of a nerve in cross-section and the equations assumed to underly potassium transfer in the absence of metabolism

from for potassium diffusion into a stirred medium, o The individual fibers are considered to constitute a single giant fiber of volume V_i bounded by a membrane whose physical characteristics are described by the constant P_1 ² Surrounding this is the lumped extracellular space, of volume V_s , bounded in turn by a surface which in frog nerve is represented chiefly by the epineurium and by the constant P_2 ² That the epineurium interferes with ionic movement was shown many years ago by the direct analytical data of Fenn *et al* (33) chloride and most of the sodium (which few will deny exist largely in the extracellular space) diffuse from frog nerve into an electrolyte free medium with an exponential time course When the chloride data

¹ Functional recovery was noted after 12 hours under these conditions and after 24 hours in Ringer

² $P_1 = h_1A_1/V_i$, $P_2 = h_2A_2/V_s$, where the h 's are the customary permeability coefficients

are plotted semilogarithmically a straight line with a time constant of 200 minutes is obtained, thus a single diffusion process is indicated and P_2 under their conditions is found to be $0.5 \times 10^{-2} \text{ min}^{-1}$. Our own preliminary determinations of P_2 from sodium measurements are closer to 10^{-2} min^{-1} , the larger value may be due to more effective stirring. The slowness of potassium escape during anaerobiosis, even when the nerves are desheathed, indicates that P_1 is substantially smaller and that the rate of anoxic loss provides a rough estimate of this constant. It may be taken as $\frac{1}{2} P_2$ for frog nerve. Additional data required are the intracellular concentrations of the cations and the volumes of the intra- and extracellular spaces. The shrinkage of frog nerve in Ringer made hypertonic with sodium chloride

Fig 4 TIME COURSE of the intracellular (K_i) and extracellular (K_o) potassium concentrations derived from the equations in fig 3 and with the constants for frog nerve

(36) agrees with available chloride data (33) in assigning (in round numbers) the volumes given in table 8. From these and whole nerve analyses the axoplasmic concentrations shown have been computed. Estimates for corresponding data in crab nerve are also given.

Figure 4 illustrates the general forms of the solutions of the equations in figure 3.³ The specific curves shown were derived by assigning the experimentally available values for frog nerve to the constants shown. The surface potassium concentration K_o goes through a maximum while the intracellular concentration K_i declines according to a somewhat less than exponential time function.

Figure 5 illustrates the time course of polarization change when the membrane potential is

³ The author is especially indebted to Dr. Jacob Lieberman for a description of a method of solution.

assumed to obey the indicated relation for a concentration cell with shunt. On a logarithmic time scale an initial 'slow phase' is followed by a nearly linear decline, which in turn is succeeded by a 'slow phase' at very late times, this is exactly as found by Lorente de N6 (16) who conducted his experiments with the nerves in contact with solution. The linear time scale provides a more correct representation of the actual rates involved and is in keeping with time curves indicated by earlier experiments (15).

Fig 5 TIME COURSE of membrane potential change as obtained by the introduction of the theoretical values for K_i and K_o into the equation shown

The analysis reveals that it is erroneous to consider the very late slow depolarization as an approach to ionic equilibrium. Figure 6 summarizes data collected over a long period to test the validity of this analysis and compares them with a theoretical curve derived from the constants shown. The theory describes potassium release for the entire 24-hour period when iodoacetate is present, in Ringer there is an initial deviation, apparently because of glycolysis, but thereafter the theoretical time course is followed. It seems necessary to conclude that the physical restraints to potassium diffusion are essentially unchanged over these very long periods as originally assumed. Moreover, another procedure is at hand for evaluating changes in permeability

from alterations in the rate of potassium escape, it may also serve to distinguish between metabolic and permeability effects by experimental agents

POST-ANOXIC RECOVERY A description of events in this case is more complex. The time constant for metabolism, i.e. $1/k$, is small, which implies rapid potassium uptake, hence boundaries which were negligible during anoxia must be considered for an analysis of recovery. For example, the depolarization effects of applied potassium are still not instantaneous in desheathed nerve (35) but occur at a rate suggesting a time

figure 7 then suffice to describe the relationships. These lead to a third order differential equation, the solution of which for potassium at the fiber surface, K_a , is given in figure 8. The variations in the concentration possess the rapidity, the overshooting, and subsequent decline to be expected from the corresponding electrical behavior (7, 15). The chief value of these calculations at present lies in the demonstration that essential

Fig 6 COMPARISON of the theoretical relation derived from the equations in figs 3 and 4, with experimentally obtained data for the net potassium release by frog nerve in nitrogen when iodoacetate (IAA) is present or absent

constant of 10 minutes, or $P = 0.1 \text{ min}^{-1}$. The relative volumes of the compartments into which such boundaries divide the extracellular space also must be known, the difference in the osmotic response of frog nerve to Ringer made hypertonic with sucrose and sodium chloride (36) may be assumed to indicate two such compartments and to provide their volumes, as given in figure 7.⁴ The lowered intracellular potassium concentration probably contributes to an elevated respiratory level following anoxia⁵ and consequently must be taken into account in a description of events. For mathematical simplicity, the nerve may be assumed to have been mounted in gas during anoxia and upon return to oxygen, the equations in

⁴ Gradients set up around individual fibers as a consequence of the diffusion restrictions by connective tissue may be a closer representation of the situation, the present assumptions may be regarded as a convenient rough equivalent

⁵ Conditions leading to a depletion of intracellular potassium (e.g. anoxia, calcium precipitants, or veratrine) augment respiration (37, 38, 24)

Fig 7 SIMPLIFIED MODEL of a gas-mounted nerve in cross-section and the equations assumed to underly potassium transfer during post-anoxic recovery

Fig 8 TIME COURSE of the potassium concentration at the fiber surface as derived from the relations in fig 7 and with the constants for frog nerve

features of post-anoxic repolarization are describable from known or measurable properties of nerve. An interesting feature of the derivation is that it is oscillatory. A concrete basis is therefore provided for examining the possibility that more rapid oscillatory bioelectrical phenomena, such as are observable in single fibers, are also due to the interplay of physical and metabolic factors, in this case the sheaths surrounding the individual axons may have an important part because of the rapidity of ionic shifts.

Energetics The encouraging results obtained in the above attempts to describe nerve behavior in terms of the ionic shifts seem to justify a

preliminary examination of some aspects of the energetics from the same standpoint. The computations to be described serve to indicate limitations of available data and to check the validity of the original assumptions.

In ionic exchange, where electrical terms cancel, the free energy change or the work done in the transfer of n mols of one of the ion species between two phases at concentrations C_i and C_o is given by

$$\Delta F = nRT \ln \frac{C_i}{C_o} \tag{4}$$

$$\Delta F = \frac{d(\Delta F)}{dt} = RT \ln \frac{C_i}{C_o} \frac{dn}{dt} \tag{5}$$

No assumptions other than those inherent in equation 4 are involved. Less general considerations, discussed previously in this symposium, lead to the same relation. The formula therefore employs the steady state concentrations (table 8) and the rate of ion transfer provided by media analyses corrected for potassium retained in the extracellular space.

In table 9 the figures obtained⁶ are compared with available heat data or with the caloric

when a) the concentrations are the same as the activities and remain unaltered and b) the standard chemical potentials in the two phases are the same. Should one or both concentrations change appreciably—as they must under prolonged experimental conditions, particularly when the extracellular fluid volume is limited—then account must be taken of the dependence of C and hence of the chemical potentials on n . The total free energy change will be the sum of the free energy changes for each ion.

THE RESTING STATE According to the postulates underlying the kinetics, the cation redistribution when the metabolic machinery is turned off is a measure of the rate of ion transfer by metabolism during the steady state. The rate of work (or the 'free energy flux') is obtained by differentiating equation 4 with respect to time

equivalents based on respiratory measurements (39). In the case of frog nerve, where the lower members of the glycolytic cycle are a major source of energy, oxidation is found to yield a free energy change exactly equal to the thermal values (ca. 0.11 cal/μM O₂ consumed, as calculated from the data in reference 40). In this particular instance the heat figures suffice for the calculation of efficiency. Because of the sparsity of information on the specific reactions involved in the other cases to be considered, heat output

⁶ Where sodium data are lacking, sodium movement has been assumed equal and opposite to that of potassium. When both ions are followed, somewhat more sodium usually is found to be involved, hence another ion probably is undergoing transfer. It may be anticipated, therefore, that some error is present even where sodium data are available.

will be assumed to equal the total free energy change for the efficiency computations

Within the limitations of the data, the efficiency is about the same for frog and crab nerve, viz., 10 per cent, when the energy turnover in the steady state is assumed to be concerned exclusively with ion transfer. Allowance for the contributions of processes concerned with other than ion distribution to energy liberation may make these efficiency figures higher.

STIMULATION A satisfactory evaluation of the energy relationships of activity involves correction not only for potassium retention in the extracellular space but for potassium reabsorption during the stimulation period as well. The use of inhibitors selective for 'activity metabolism' (41) may serve to minimize the second complicating factor. The available data must presently be

change during recovery, we obtain an efficiency of about 45 per cent for crab nerve and of 5 per cent for frog nerve. The high value for invertebrate tissue indicates that the restoration of the normal ion balance is a major concern of recovery, the involvement of some recovery reactions in other processes would lead to a prohibitively high efficiency. It is hardly likely that the use of heat rather than free energy data in the calculations is in itself responsible for this high value. The low figure for frog nerve cannot be taken seriously until an estimate is available of the potassium failing to appear in the medium during stimulation because of active reabsorption, a high absorption rate would give a spuriously low efficiency.

These considerations do not imply a direct dependence of impulse transmission on recovery

² At 0°C

regarded on the low side. In the case of crab nerve this error is probably small because of the slow recovery process.

Table 10 gives available thermal (39) and calculated figures for the single impulse. In frog nerve the initial heat is of the same magnitude as the free energy decrease, but this may be regarded a coincidence since in an ideal solution no heat would be evolved as a result of mixing. Some heat transfer may be anticipated from the non-ideality of the system but, unless other than simple dilutions are involved within the fiber, this is probably small. It is noteworthy that the decline in initial heat with continued repetitive stimulation (39) is in the direction to be anticipated from the changes in concentration and in the associated activity coefficients.⁷

Again assuming that thermal data (i.e. the recovery heats) measure the total free energy

⁷ Dr. Hearon very kindly provided the theoretical basis for these remarks on initial heat

processes. This would be contrary to the conclusion reached earlier from the washing and recharging experiments. Rather, recovery may be regarded as concerned a) with minimizing the extracellular accumulation of potassium and b) with preserving an adequate reserve of intracellular potassium for impulse production. On this basis the interference with recovery respiration achieved recently with azide (41) need not be expected to impair conduction as long as the potassium levels within and without the fibers are not altered excessively, but, as in the case of inhibitors less specific for 'activity metabolism,' azide may be expected to hasten the onset of failure during continual activity.

NOTE ADDED IN PROOF

A series of publications by Feng and his associates in the 1950 issue of the *Chinese Journal of Physiology*, received subsequent to the submission of this manuscript, should be noted, of particular interest is the paper (*Chinese J. Physiol.* 17:247, 1950) corroborating the correlation be-

tween potassium release and depolarization indicated by our early indirect experiments and discussed with Dr. Feng prior to publication (7, 8). Limitations of space have compelled a scrupulous neglect of recent pertinent data on muscle, however, attention must be called to the work of Fleckenstein and his associates, recently summarized in detail (*Arch Exper Path Pharmacol* 212: 54, 1950). Their results are of particular importance in indicating significant relationships between electrochemical changes and muscle short-

ening under conditions similar to those which have been described for nerve.

The earlier phases of this work were supported by grants from the Division of Research Grants and Fellowships of the National Institutes of Health, United States Public Health Service, and from the American Philosophical Society. The conscientious technical assistance of Miss T. Abramsky and Mrs. E. Bowman is gratefully acknowledged.

MACHINE EFFICIENCY OF ASSIMILATIVE PROCESSES

JOHN O HUTCHENS¹

From the Department of Physiology, University of Chicago, Chicago, Illinois

THE EFFICIENCIES with which living organisms convert food materials to protoplasmic constituents or energy stores during growth, repair, or maintenance are of economic importance. They also carry important theoretical implications for students of intermediary metabolism. Investigations dealing with this problem have been conducted using organisms ranging from mammals to microorganisms (Phototrophic nutrition poses special problems and will be neglected here). The purpose of this paper is to analyze some of the results obtained in an attempt to estimate the efficiency with which such conversions can or do occur. The varied and frequently arbitrary conventions used by different workers will be examined, and the doubts and difficulties which beset students of the problem will be emphasized. Conventions which make possible the application of thermodynamic as well as thermochemical analysis to studies of heterotrophic nutrition are introduced. It is hoped that these will encourage further investigation and thermodynamic analysis particularly in mammalian nutrition.

The discussion which follows is divided into five parts: 1) Definition of the machine efficiency of assimilation; 2) problems connected with ascertaining this efficiency; 3) efficiencies reported or calculated here for microorganisms; 4) factors affecting assimilation efficiency; and 5) calculation of a machine efficiency of assimilation in the rat.

The literature cited is intended to be illustrative rather than comprehensive and it is left to the reader to consult original papers for details of methods and results. All free energy calculations are based on values to be found in previous publications (1, 2).

1. DEFINITION OF MACHINE EFFICIENCY OF ASSIMILATION

Two widely differing measures of assimilation efficiency are in common use. Thus, in mam-

malian nutrition studies, efficiency is ordinarily calculated (3) as $100 \times \text{calories stored} - \text{assimilable calories ingested}$. In studies on microorganisms (1, 4, 5) efficiency has been calculated as $100 \times \frac{\text{free energy cost of assimilative reactions}}{\text{free energy available from catabolic reactions}}$. An efficiency calculated in either way is commonly called the 'efficiency of growth'. Growth in the complete sense involves cell division which requires energy (movements of cytolinesis and karyokinesis, creation of new surface, etc.) and organization with an unknown entropic contribution. Most of the studies referred to below, however, involve simply the accretion of protoplasm or of stored materials such as glycogen or fat. I shall therefore speak of efficiencies of assimilation rather than of growth.

The two different customs referred to above represent basically different approaches to the problem of assimilation. On the one hand, the calories in corn conserved by a cow are of economic interest. On the other, the ratio of free energy required to that made available for assimilation may either support or embarrass particular ideas about intermediary metabolism and the mechanisms whereby energy is trapped and utilized. I shall refer to efficiencies calculated in the first way as 'caloric conservation efficiencies' or to the 'caloric conservation coefficient'. For the quantity $100 \times \frac{\text{free energy cost of synthesis}}{\text{free energy available from catabolism}}$ I shall use the term 'machine efficiency of assimilation' (6).

By free energy available from catabolism I shall mean that over and above a basal level² observed in nonassimilating control organisms. In microorganisms this 'basal' level is ordinarily a fasting level (1, 5). In mammals, as we shall see, the maintenance level of metabolism serves

² Subtraction of the endogenous metabolism of microorganisms may be questionable in other connections (7). For the present purpose, failure to do so would imply that the cost of other processes during assimilation is zero. In many cases the correction is inconsequential, particularly if the endogenous metabolism is a small fraction of the exogenous.

¹ Unpublished investigations from the author's laboratory were supported by the Wallace C. and Clara A. Abbott Memorial Fund of the University of Chicago.

best as the base (S) Subtraction of a maintenance metabolism in microorganisms would be preferable, but this is difficult to establish The fact that metabolism during assimilation in microorganisms is many times (5- to 40-fold) greater than the endogenous rate minimizes the error involved

2 POSSIBILITY OF ESTABLISHING MACHINE EFFICIENCIES OF ASSIMILATION

At first glance, calculation of the efficiency with which free energy available from catabolism is captured for purposes of assimilation appears simple Assimilation in principle consists of the chemical conversion of one or more compounds to some other compound(s) Given the free energies of formation (ΔF_{form}) of reactants and products, their activities, and the number of mols converted, the free energy required is calculable The same being true for catabolic reactions, the energy available and thence the machine efficiency of assimilation emerge A closer inspection of the details involved, however, forces a more pessimistic outlook

The most glaring present-day deficiency in the knowledge needed for this purpose is our complete ignorance of ΔF_{form} values for proteins Indeed the values for many amino acids are unknown, and are not calculable by usual procedures (9) Entropy values associated with structural improbabilities in proteins further complicate the matter It is no wonder therefore that those who have attempted to estimate assimilation efficiencies have either eliminated protein synthesis by omitting a nitrogen source (2, 5) or have made arbitrary assumptions regarding the energy cost of protein synthesis (1, 4)

The above difficulties regarding the cost of protein synthesis could probably be removed by appropriate experimental work Heat-capacity measurements at low temperatures on a few amino acids and a few crystalline proteins would permit calculations regarding entropies from the third law of thermodynamics There would still remain certain difficulties not so easily overcome These concern carbohydrate and fat formation as well as protein formation

What shall we say is the work done when an animal converts a food, say glucose, to fat? The overall process is exergonic Thus for glucose to triolein assuming passage through a C_2 stage with the necessary generation of 2 CO_2

If we accept this at its face value, no work is done and the efficiency of assimilation is zero or indeterminate This situation is not confined to mammalian nutrition or to foods like glucose Thus Blum *et al* (2) were faced with the problem of assimilation of ethanol with starch being synthesized Again the overall reaction under their conditions was exergonic

The escape from the above dilemma proposed (2) is something more than a convention Invoking the known intermediary metabolic steps and the fact experimentally demonstrable in their experiments that acetic acid appears at least transiently in the conversion of ethanol to carbohydrate the authors reasoned as follows Energy is released in the oxidation of ethanol to acetate, some further energy is released by the complete combustion of a fraction of the acetate, to convert the remainder of the acetate to amylose is an endergonic process Taking the work done as that of converting the acetate to amylose, and the energy available as the sum of the two oxidative processes, these authors found an efficiency essentially the same as that found for acetate oxidation and assimilation in *Chilomonas*

The above line of reasoning can be applied to the glucose-to-fat conversion cited above Thus glucose in all probability is first converted to two C_2 fragments + 2 CO_2 + water To synthesize fat from these C_2 fragments is an endergonic process A more detailed analysis of this situation is given in section 5 The important point to be recognized is this Whenever in an overall exergonic process, a point is reached at which the remaining steps are endergonic, the problem for the biologist is to ascertain how efficiently the free energy yielded in the exergonic steps is captured to drive the endergonic ones This is no violation of the principle that the overall free energy change is independent of the path (10) This must and will still be true However, one does not have to be frightened into ignoring everything except the overall ΔF Common sense,

if nothing else, tells us that if endergonic steps occur, they must be driven. Other steps in the same overall process are candidates for this function on an equal basis with steps in parallel reactions.

The above convention introduces certain difficulties not encountered in simpler situations. Thus in the ethanol-starch conversion, the concentration of the intermediary acetate affects the actual ΔF values of both the exergonic and endergonic reactions. In the glucose-to-fat conversion the identity and concentration of the C_2 fragment are of critical importance. These however are transient difficulties to be overcome by future studies of intermediary metabolism and quantitative analyses of the cells or fluids concerned.

Finally we may consider the methods available for establishing the percentage of available food-stuff degraded and the percentage assimilated. These methods differ in detail but are in essence the same whether the assimilating organism be a bacterium or a mammal. Three mutually supporting methods are available.

1) Direct chemical analysis This is most easily practiced with mass cultures of microorganisms from which aliquots can be withdrawn from time to time. It is the least equivocal of the methods and knowledge of the details regarding conversions occurring is limited only by existing analytical methods and the experimenter's patience.

2) Calorimetry By measuring the extra heat produced by an organism presented with a limited and known amount of substrate, the degradation-assimilation ratio can be calculated under certain circumstances (2, 5). Ordinarily chemical analyses or respiration measurements must be conducted to confirm the assumptions regarding the reactions responsible for generation of the heat.

3) Respirometry The extra O_2 consumed and/or CO_2 produced can be used in place of heat production as above. Again auxiliary information from direct analyses or heat measurements may be required.

The practical difficulties met with in calorimetry and respirometry for the above purposes are well illustrated in figure 1 taken from an experiment carried out in my laboratory (11). This figure might just as well represent heat or CO_2 production as O_2 consumption.

It is a well-established fact that in such ex-

periments the extra O_2 , CO_2 or heat is less than that theoretically derivable from the added substrate (2, 5, 7). It is commonly assumed that when a sharp break occurs in the upper curve the added substrate has been exhausted through combined degradation and assimilation. With glucose as substrate this has been demonstrated analytically (5). With other substrates it seems the only explanation compatible with other known facts (7, 12). It would be comforting, however, to have direct analyses for other substrates at the time of this sharp break in the curve.

The difficulties inherent in this method of establishing oxidation-assimilation ratios stem from the following:

1) The endogenous rate of O_2 consumption falls off with time. In yeast this decline is first order (5). In *Chlamydomonas* there is usually an abrupt change in rate after 2 to 3 hours (lower curve, fig. 1).

2) The rate of O_2 consumption following the exhaustion of added metabolite exceeds even the original endogenous rate for some time. This excess in rate after the break is roughly proportional to the amount of substrate assimilated (7, 11).

The net effect of the above is to indicate a progressively greater percentage of substrate catabolized the longer one waits to assess the gas or heat increment. In my opinion the best choice one can make is ΔY_1 (fig. 1). To take the increment at any later time probably includes metabolism of material recently assimilated. This problem has long plagued experimenters in this field, but it has become particularly important in some of our recent studies.

So long as a large fraction of added substrate is oxidized and the calculated efficiency is low it carries no embarrassing theoretical implications. However, in experiments on *Chlamydomonas* metabolizing acetate we have recently recorded oxidation-assimilation ratios near 1.4. With starch as the end product this implies an efficiency near 50 per cent under our conditions. Furthermore, the energy captured is approaching the maximum which can be accounted for by high energy phosphate bond ($\sim P$) formation. Should the apparent efficiencies increase by much, the number and/or energy value of $\sim P$ bonds formed would have to be increased, other mechanisms of energy capture would have to be found,

on our assumptions regarding the cost of synthesis would have to be revised

To summarize, in preparation for the next section. So long as the end product of synthesis is carbohydrate or fat, quite accurate calculations of the efficiency of assimilation frequently can be made. When protein is being synthesized no exact calculations are possible. Often the overall reaction of assimilation is exergonic. Only by splitting it into its exergonic and endergonic components can any calculations of efficiency be made. With these reservations I present the data on microorganisms below.

3. BEST PRESENT ESTIMATES OF ASSIMILATION EFFICIENCIES

The most precise calculations of the efficiency with which assimilation occurs have been made using data obtained with microorganisms (1, 2, 4, 5). In a pioneering effort Baas-Becking and Parks (4) in 1927 analyzed the data of many workers who had studied the growth of autotrophic bacteria. The data available to them gave moles of CO_2 fixed per mol of inorganic energy yielding material oxidized. Defining efficiency of growth as I have defined machine efficiency of assimilation they obtained values near 6 per cent for most forms, hydrogen bacteria being exceptional with an efficiency of 26 per cent.³ Until the recent studies of Blum *et al.* (2) on *Chilomonas* the figures for hydrogen bacteria were the highest ever reported.

In making their calculations Baas-Becking and Parks (4) made the simplifying assumption that all of the CO_2 fixed was converted to solid anhydrous glucose. The equation used by them was

With CO_2 as a carbon source this simplifying assumption leads to a probably negligible error in view of other uncertainties. Thus, if the amylose hexose unit of glycogen or starch (1) is taken as the product in the above equation $\Delta F_{298} = +118,862 \text{ cal}$.

For that fraction of the CO_2 converted to fat, using triolein as typical

³ See also Burk (6)

In the absence of free energy values for protein formation we can do no more than state the value of $\Delta H = +126,000 \text{ cal}$ per mol of CO_2 converted to egg albumin based on a heat of combustion of 5.7 cal/gm. The efficiencies calculated (4) for autotrophic bacteria would therefore be increased to no more than 7 to 8 per cent for most forms if closer account were taken of the end products.

When we turn to heterotrophic nutrition, the assumption that solid anhydrous glucose is the end product of synthesis can no longer be employed without introducing an intolerable error.

Fig. 1. TIME COURSE of O_2 consumption following addition of 8 μmols Na acetate to suspension of *Chilomonas* at pH 6.0. Temperature 25°C, 4.0 ml cell suspension 3.5×10^6 cells/ml.

Thus, if 5 per cent glucose (0.28 M) itself is the substrate

On the other hand, taking the actual final product as amylose hexose units in saturated solution yields

Large errors (a factor of 2-3) in estimating the

work done can easily be introduced in this way. In all of the studies summarized in table 1 adequate account was taken of the final product of synthesis. In making calculations from Barker's (7) data I have accepted his conclusion that only carbohydrate was formed and used the amylose hexose unit as the final product taking as its free energy of formation $-217,851$ cal (1). For lack of space I have dealt only with Barker's data involving acetate and butyrate. Data presented by Wilson and Peterson (13) and Fulmer (14) could also serve as the basis for interesting calculations but assumptions used would have to be explicitly stated.

It will be seen from table 1 that reported values for the efficiencies of assimilation of organic substrate by heterotrophic forms fall in the same range as those reported for autotrophic bacteria (4). Whether these are the highest possible efficiencies will be discussed below.

4 FACTORS AFFECTING ASSIMILATION EFFICIENCY

The natural tendency of investigators studying the efficiency with which substrates are assimilated has been to employ temperatures, pH values, salt concentrations, etc., optimal in the sense that they produce the most rapid growth of the organism. The carbon and energy source has frequently been below optimal in the above sense. There is no *a priori* reason to assume that conditions which lead to most rapid cell division or increase in mass of protoplasm also lead to the most efficient assimilation. Indeed there is evidence to the contrary.

Brücke (15) studying anaerobic assimilation of glucose by yeast found that monoiodoacetate (IAA) at a concentration which inhibited fermentation by 86 per cent reduced conversion of glucose to glycogen by only 57 per cent. The experiments were of such duration as to preclude any explanation based on temporary nonsteady state phenomena. The improved assimilation-fermentation ratio raised the efficiency of the process from ca 2 per cent to ca 6 per cent. A similar effect of fluoride on assimilation of glucose by yeast has been reported (16). These findings may be interpreted as follows. The fermentation of glucose is inhibited by IAA and fluoride while the assimilative reactions from glucose to glycogen are unaffected. Any existing excess of energy production over that actually required for synthesis would thus be reduced.

The converse of the above situation is seen in the effect of such inhibitors as IAA and fluoride in reducing the percentage assimilation of substrates such as acetate and butyrate (12). Here the assimilative pathway is blocked while energy release is essentially unaffected. Cyanide and azide reduce assimilation of substrates but their effect is not easily explained. Diminophenol in appropriate concentrations leads to complete oxidation of acetate in yeast (5) and *Pseudomonas* (12), i.e. zero assimilation efficiency. Presumably this results from interference with oxidative generation of $\sim P$ bonds (17).

The report of Blum *et al* (2) that the oxidation-assimilation ratio for acetate is greater in the presence than in the absence of a nitrogen source cannot at present be interpreted. Protein synthesis may require more energy than carbohydrate or fat synthesis. On the other hand it may be less efficiently accomplished. In any event the finding serves as a warning against accepting assimilation efficiencies obtained in the absence of a nitrogen source as a measure of the 'efficiency of growth' (5).

Two factors which might logically be expected to influence assimilation efficiency have been inadequately studied in microorganisms. These are temperature and the nutritional state of the cell. In my own laboratory we have been unable to detect any change in the efficiency of synthesis of starch from acetate by *Chilomonas* over the temperature range from 15° to 30°C. Regarding nutritional state, starving cells for 24 hours has little if any effect on percentage of acetate assimilated. Raising the starch content of the cells by prolonged exposure to acetate in the absence of a nitrogen source (to prevent growth) simply reduces the rate at which acetate is oxidized and assimilated rather than changing efficiency (11).

5 MACHINE EFFICIENCY OF CARBOHYDRATE ASSIMILATION IN THE RAT

As stated earlier it is common practice in studies on mammalian nutrition to calculate the caloric conservation efficiency. If calculations analogous to those given above for microorganisms have appeared, they have escaped my notice. I have attempted some crude and tentative calculations below with three objects in view. First, to stimulate others to make more precise calculations, second, to stimulate the reporting of data which will make such calculations possible, and finally to show that, to a first approxi-

mation, mammals do not differ radically from microorganisms in the efficiency with which they capture free energy for assimilative purposes

Out of the vast body of knowledge regarding mammalian nutrition relatively few studies are suitable for the present purpose. Measurements of the specific dynamic action of foods measured above the basal (fasting) level must be rejected. Between the basal and maintenance levels of metabolism food apparently serves largely to spare the body stores which otherwise would have to be metabolized. Only above the maintenance

On the basis of the above figures the mean caloric conservation efficiency is 77.5 per cent since only 22.5 per cent of the calories theoretically derivable from the extra fed starch appeared. In order to calculate a machine efficiency of assimilation we must make certain assumptions regarding the end product of the assimilation, the pathway of metabolism, and the conditions under which the conversions occurred.

That the end product stored was chiefly fat there can be little doubt. The rise in R:Q values produced by the extra starch indicates this, and

TABLE 1 MACHINE EFFICIENCIES OF ASSIMILATION OF HETEROTROPHIC MICROORGANISMS

ORGANISM	SUBSTRATE	PRODUCTS	METHODS	EFFICIENCY, %	REFERENCE

¹ Energy cost of protein taken as that of carbohydrate of equal carbon content

level does net synthesis occur. Forbes *et al.* (8, 18) have shown that above the maintenance level, i.e. when net synthesis is occurring, the specific dynamic actions of foods increase sharply. Above the maintenance level the extra heat produced per unit of ingested food is constant over a considerable range (8).

I have chosen as the basis of the computations which follow the data of Kriss *et al.* (19). In these studies rats were first established on a maintenance ration of calves' meal. The average daily heat production was 15,888 cal. When an additional 2.2 gm of starch having a caloric equivalent of 8228 cal were fed the mean daily heat production rose to 17,736 cal. The difference of the means was 1848 cal with a standard error of 242 cal.

storage of any appreciable portion of the starch as glycogen would produce an improbable rise in the glycogen content of the tissues. I shall assume therefore that fat was the product of synthesis and use triolein to represent this.

The remaining assumptions which I shall make can be quarrelled with in almost every detail. The absurdities are purposeful, however, in that the pathway and conditions chosen yield what is probably the maximum machine efficiency. Thus I shall assume that the C₂ particle derived from glucose which serves as the starting point for fat synthesis is the acetate ion at a concentration of 10⁻⁶ molar. Trapping the C₂ particle at an energy level above acetate would decrease the work of synthesis more on a percentage basis than it would decrease the energy made avail-

able for driving the reaction. Other assumptions can be similarly shown to work in this way.

I shall ignore the heat and free energy changes attendant on hydrolysis of the starch, and the hydration, solution and dilution of the derived glucose. Starting then with glucose at a concentration of 90 mg per cent (0.005 M) I shall write the following overall equation:

I have calculated $\Delta H_{310} = -176,926$ cal for this reaction. The heat value given by Kriss *et al* for their starch (3.72 cal/gm) corresponds to a little more than monohydrated amylose units (MW = ca 182). On this basis they fed 0.012 mols/day. The above equation therefore predicts an extra 2100 cal/day. This figure is well within the permissible range of 1364 to 2332 cal (mean ± 2 S.E.).

To estimate the energy available and required for the conversion I shall break the overall reaction into two components:

On this basis the machine efficiency is 20.8 per cent. As mentioned above alterations in the adopted scheme to make it more nearly compatible with the realities of intermediary metabolism will tend to lower the efficiency. I can only plead that I would have made such changes if I could. Until the identity of the C_2 fragment, its concentration, and energy of formation are known, a better calculation will be difficult. One point is perhaps worth comment. In classical schemes of representing carbohydrate to fat conversions generation of gaseous O_2 is employed in partial reactions. The scheme I have employed of reserving the H^+ -electron pairs for subsequent reductions in fat formation with generation of water is more realistic. It was to achieve balance in this regard without appealing to outside systems that I accepted a slightly high figure for heat production. Trapping the C_2 fragment at a more reduced stage than acetate would allow greater latitude in proportioning oxidation and fat synthesis.

It would thus appear that, employing similar conventions, the machine efficiency of assimilation in a mammal may be quite similar to those observed in microorganisms. Other and more adequate calculations of this type should of course be made. In particular, variations in food-stuff, feeding schedule, and end product synthesized may alter the efficiency. The examples cited in section 4 bear witness to the fact that the efficiency which does occur may have little relation to the maximum possible efficiency.

AMERICAN SOCIETY OF BIOLOGICAL CHEMISTS

Symposium on Cytochemistry

Chairman E L TATUM

LOCALIZATION OF SUBSTANCES IN CELLS

ARTHUR W POLLISTER, MARION HIMES AND LEONARD ORNSTEIN

From the Department of Zoology, Columbia University, New York City

IT is very gratifying to a cytologist to have an opportunity to address The American Society of Biological Chemists in a Symposium on Histochemistry. Until the later decades of the nineteenth century, cytology and biochemistry were not at all distinct, both were prominent parts of the broad field of physiology. The microscopic structure of tissues always appeared as part of the textbooks, and many of the great physiologists speculated on the possible localization of functions within the structural components of cells. Claude Bernard, for example, suggested that the cell nucleus, the only structure then recognized to be common to all cells, was concerned with synthetic functions—a view that was later brilliantly confirmed by the demonstration that when a single-celled organism is cut in two pieces, only the nucleated half can carry on the syntheses essential for growth. It was under the stimulus of such ideas that in 1869 Miescher devised a method of isolating masses of nuclei from the remainder of the cell, the cytoplasm, and subjected them to chemical analysis. Almost coincident with Miescher's discovery of the very unusual chemical composition of the nucleus, Abbé's greatly improved compound microscope became available—and in the hands of Flemming and others this instrument led to observations of the remarkable nuclear phenomena during cell division and fertilization, which marked the beginning of modern cytology. These early workers by no means regarded themselves as in distinct fields, each was well aware of parallel progress by the other group. Miescher, for example, performed experiments to show that the specific staining of nuclear substance was due to combination of his nuclein with the basic dye methyl green, while it was a cytologist, Altmann, who

gave the name nucleic acid to the acidic component of Miescher's nuclein. Beginning early in the twentieth century, however, there developed among both cytologists and biochemists a tendency to work under domination of particular standardized techniques rather than under stimulus of the broad problem of correlation of biological function with intracellular organization. Such specialization eventually led to the almost complete isolation of these two fields, which prevailed until fairly recently. Within the last 10 years happily there has been a reorientation, a return to recognition of the priority of the problem of the significance of intracellular organization. Today there are many cytologists who are anxious to work with biochemists, even to attempt to master some of their techniques, and there appear also to be biochemists who are willing to attempt to localize activities within morphological components like the nucleus, mitochondria, and microsomes.

It is the great charm, the fascination, of study of the microscopic structure of organisms that the shapes of tissue cells and intracellular morphological changes are often so beautifully expressive of the function of the cell. This is well shown by the exocrine glandular cell, such as that of the pancreas, which I shall later use to illustrate the methods of localization of nucleoprotein in cells. This cell is in the form of a pyramid, usually six-sided, with sides in contact with 6 other cells. The base of the pyramid is adjacent to the blood vessels, the apex is in communication with the duct system of the gland which opens into the small intestine. The fine details of cells are usually studied in thin sections, and the probable structures visible in such a thin section are shown schematically in figure 1. The

most conspicuous object is of course the nucleus, within which are scattered masses of chromatin, and a conspicuous nucleolus. The duct end of the cell is largely occupied by a mass of spherical secretory granules, concealed within which is a pair of centrioles, which are organs of cell division. Scattered throughout the cytoplasm are mitochondria, and in the basal region, perhaps also

Fig 1 DIAGRAM of structural features in section of an exocrine glandular cell of the pancreas, after Pollister, 1951 (1). Parts of the boundaries of adjacent cells in the secretory unit, or acinus, are outlined and the blood capillaries near the basal end of the cell are indicated. Abbreviations: *c*, centriole, *eg*, basal ergastoplasmic zone, containing submicroscopic microsomes (The microsomes have not been observed in this type of cell. It is assumed from results on liver cells by Hogeboom, Schneider, and Palade, 1948 (2), that: *a*) the cytoplasmic region of high nucleic acid content must be the site of a major accumulation of microsomes, *b*) the microsomes are asymmetrical, probably thread-like, and *c*) these asymmetrical bodies tend to become oriented parallel with the long axis of the cell, as suggested in Pollister, 1940 (3)), *mg*, mature granule, *ig*, immature granule, *m*, mitochondrion, *n*, nucleus, and *bc*, blood capillary.

elsewhere, there is reason to believe there are rather densely packed sub-microscopic thread-like microsomes. The actual structure is shown in the phase contrast photomicrograph of an unstained one-micron section of a rat's pancreas (fig 2 A). This cell has one principal function, to elaborate the granules which are thrown out into the duct system when the gland secretes the pancreatic juice. This phenomenon clearly suggested that the granules are the precursors of the constituents of the pancreatic juice, for which reason they have long been called *zymogen granules*.

As you doubtless all know, this relation to the pancreatic enzymes is supported by the observations of Van Weel and Engel (4), that the peptidase activity of fresh slices of pancreas is directly related to the granule content of the cells. The central problem of intracellular pancreatic function, then, is how in a few hours the cell elaborates a large mass of zymogen granules, which has been estimated to be as much as one-fifth of its own dry weight. Morphologically this process has been well described in beautiful studies, first by Hirsch (5) and later by Duthie (6). In the quite intact gland, drawn out onto a warmed slide through a ventral incision in an anesthetized mouse, they followed the development of individual granules. The granule appears first as a small body in the basal zone, it slowly enlarges and becomes progressively more dense as it moves toward the final position for discharge. There are also marked concomitant changes in the nucleolar part of the nucleus, and in the appearance and staining reactions of the basal part of the cell.

The pancreas is a typical component of a specialized tissue, and like other cells has two categories of visible structures: *a*) the granules which are primarily an expression of the unique cell function, and *b*) the nucleus, mitochondria, centrioles, and probably microsomes which are much like those of all other cells, and which we accordingly are accustomed to consider as the essential cell organelles which are concerned with cell maintenance and other functions which underlie the special tissue activity. These structural features of cells are fairly well worked out, although the picture will surely soon be greatly enriched by developments in electron microscopy. The major unsolved problem is to make this picture meaningful in terms of cellular biology, to determine what specific functions may be attributed to the visible structures in cells. There was a period—not so long ago—when it seemed as if physiologists were satisfied to attribute a majority of fundamental intracellular activities to the properties of a formless sort of soup, which had as its chief asset the heritage of a fine old name—*protoplasm*. I suppose this was patterned after the distribution of hemoglobin in the erythrocyte, which is a most atypical cell indeed. At any rate, there has been in recent years a marked change of viewpoint. As some of the other speakers in this symposium will amplify, it is becoming evident that many important physiological mechanisms are as sharply restricted to

one particular cell component as the mechanisms for gene distribution and photosynthesis have long been recognized to be

The localization of substances within cells, to which I am to give particular attention, often clearly indicates the function of a particular part of the cell. There are two main ways by which such a qualitative chemical analysis may be carried out: one may deal with isolated masses of a particular structure, as Miescher did with nuclei, or one may by direct microscopic observation visualize the substance within a single intact cell.

Improved methods of isolation have added much information about the chemical composition of nuclei, mitochondria, and microsomes of animal cells and the plastids of plant cells. The sample may be large enough so that a variety of analytical procedures can be carried out to give a comprehensive average composition of structures from a population of billions of cells. If one performs the arduous task of analysis of all fractions in the isolation procedure, as Doctor Hogeboom and his collaborators (2) first did, it is possible to make the very important demonstration that a chemical compound, or a specific activity, is restricted to a particular category of cell component. Thus, it has been repeatedly demonstrated that the desoxyribose nucleic acid of a mass of tissue is all recoverable in the isolated nuclei. Furthermore, if one counts an aliquot from the sample, he can estimate the number of components in the sample, and by division of the figures from the analysis of the sample arrive at an average amount per component. Boivin, Vendrely and Vendrely (7) first did this with isolated nuclei from a variety of beef organs and from spermatozoa. They noted the average amount per tissue nucleus was the same for all organs, and was approximately twice that of the spermatozoon (table 1). Since this was identical with the relationship between the double set of chromosomes of the tissues and the single set of the spermatozoon, they concluded that the amount of nucleic acid was constant for each chromosome set. Davidson and Leslie (10) have suggested that with the DNA determination as a base, one can estimate the number of cells in a sample, and by reference to this express other analytical results as amount per cell. This will, of course, indicate the real situation within each cell only if there is reason to suppose that all cells are alike. The method must therefore often

tend to obscure the very aspect of chemical composition which may be most important, namely the variation of cellular composition with cyclical or progressive cell phenomena.

Most workers seem to be well aware of the fact that there are further difficulties in extrapolating to the cell, which arise from the procedures used in isolating components. The purity of the isolation is always problematical, and even though the fraction may obviously contain only a negligible contamination with other structural elements, there is always the possibility that material may be either washed out of the components or adsorbed from other sources.

TABLE 1. DNA PER NUCLEUS IN BEEF TISSUES

ORGAN ¹	AMOUNT ¹ ($\times 10^{-9}$ mg.)	NO. OF NUCLEAR TYPES	PROBABLE CHROMO- SOME NO.
Thymus	6.4	1	Diploid
Liver	6.4	2	Diploid
Pancreas	6.9	6	Diploid
Kidney	5.9	10	Diploid
Sperm suspension	3.3	1	Haploid

¹ After data of Vendrely and Vendrely, 1948 (8). The major number of nuclear types are estimated from common textbook descriptions of the histology of the organs. Table reproduced from Polster, Swift, and Alfert, 1951 (9).

Assuming that these difficulties are obviated, the best that the method of isolation alone can yield is data as to the overall average composition and the restriction of a substance to some members of one category of cellular component, it obviously falls far short of giving specific information at the level of a single cell. Thus, from the data of table 1 alone, one could not say whether there might not be in any sample a considerable, though constant, fraction of the nuclei which had no desoxyribose nucleic acid at all. As a matter of fact, such a question has not, so far as I know, ever been raised, because, as everyone knows, there is excellent cytological evidence from application of the highly specific Feulgen reaction for desoxypentose that every single nucleus contains an abundance of desoxyribose nucleic acid. While, as Dr. Hogeboom will tell you, chemical analyses indicate that certain important intracellular respiratory mechanisms appear to be confined to the mitochondrial fraction, it by no means follows that these occur in every individual mitochondrion. The most conclusive evi-

dence that this is so appears to come from the cytological observation that when cells are stained vitally with a dye Janus Green B, which is readily reducible to the colorless leucobase, every mitochondrion remains brilliantly colored in sharp contrast to the colorless remainder of the cell. I respectfully request that you keep in mind for a few minutes these excellent illustrations of the interdependence of the isolation and cytological techniques, while I describe our efforts at adaptation of some chemical methods to the study of individual cells. Compared with the certainty and variety of the analytical techniques which can be used upon a sample of several milligrams of isolated components, our resources will seem extremely limited. Few though they are, however, these are the only gateway which certainly leads directly inside the individual cell.

The possibility of applying analytical methods to achieve the visualization of substances *in situ* within the cell has intrigued many cytologists, histologists and pathologists, and there have been numerous sporadic outbreaks of enthusiasm for one or another supposedly satisfactory method, the devotees of which have proceeded to describe the localization of the particular substance in a wide range of cell types. Many of these are evaluated critically in Lison's *Histochemie Animale* (11). The ideal localization is of course that which can be carried out upon the intact living cell, but in practice this is necessarily limited to substances with strong natural absorption, which occur in relatively high concentration. When this is visible color, like that of chlorophyll or hemoglobin, visualization is obviously easy. It has long been known that with ultraviolet light, absorption within the living cell is very pronounced in the chromatin of the nucleus (fig. 2D). In 1936 Caspersson (15), in his masterly doctoral dissertation, proved that the chief basis of this was the natural high specific absorption of the purine and pyrimidine components of the nucleic acid of chromatin. Originally, this seemed to offer an opportunity for localization of nucleic acid within living cells, but it is now becoming generally recognized that the interpretation of the ultraviolet absorption spectra of living cells is by no means unequivocal. A great variety of intracellular substances (for example nearly all aromatic compounds) absorb the same part of the ultraviolet spectrum as does nucleic acid, and there seems no way of distinguishing among these in the living cell. Other

difficulties arise from non-specific light loss and from the injurious action of the radiation (see Ris and Mirsky, 16). Consequently it is clear, as Caspersson himself has stated in his latest publication (17), that living cells are as a rule unsatisfactory objects for ultraviolet absorption analysis. It is far better to analyze fixed tissues, in which the specificity of the ultraviolet absorption can be checked by subjecting the cells to a variety of solvents and enzymes, as well as to confirmatory specific color tests and stains.

We must then, work mainly with what is called fixed material, and our efforts must be of course confined to those analytical procedures which will not alter the cellular structure beyond recognition. This immediately excludes a great many methods which are too drastic to apply to sections. A further limitation arises from the fact that during the process of fixation there is abundant opportunity for loss of and extensive redistribution of inorganic and smaller organic molecules. This has been repeatedly demonstrated to take place, and the necessity for caution in interpreting the results of microchemical tests for these substances has been frequently stressed¹. Thus, localization is practically limited to the compounds of large molecular size, which are precipitated or coagulated by fixation. By some special methods certain lipoidal substances can be rendered insoluble, but in most cells the common acid fixation may be assumed to leave essentially unchanged in amount and distribution only the proteins and nucleic acids. These are, in fact, the basis of the common histological picture of the cell, in which the nucleus is stained with basic hematoxylin, the cytoplasm with acid eosin. From the standpoint of nucleoprotein analysis, such fixation is of great advantage, for it is a sort of preliminary fractionation. The specific methods of demonstrating the distribution of protein and nucleic acids in the glandular cell, which was described previously, will illustrate the modern application of qualitative chemical cytology.

Analyses of animal tissue have shown that the bulk of the cellular material, roughly 60 to 80 per cent of the dry weight, is protein. This pro-

¹ Localization of certain mineral elements does seem possible if frozen-dried material is ashed (see Scott, 18) and many other elements can be localized by x-ray absorption analysis of frozen-dried tissue. Also the method of radioautography can probably be extended to the levels of intracellular localization.

Fig 2 SERIES of photomicrographs of pancreatic glandular cells, to show structure and the results of various techniques of localization of nucleic acids and proteins

A From a tadpole of the green frog, *Rana clamitans*, tissue well fixed to show all structural details Technique Double fixation in osmic acid followed by formalin, embedded in n-butyl methacrylate and sectioned at 1μ , using a Spencer microtome with slow feed attachment and a glass knife, mounted in Cargille's refractive index oil (n_D 1.460), photographed with Zeiss phase contrast equipment, using a Pointolite lamp, Wratten 58 filter, and Kodak M Plates, $\times 800$ B From the salamander, *Necturus*, after the Millon test for protein Technique Fixed in Champy's osmic-chromic-bichromate mixture, embedded by the methyl benzoate-celloidin-paraffin method, and sectioned at 6μ , Millon reaction for total protein as described in Pollister (12), photographed on Wratten M plates, using an AH4 type mercury vapor lamp, from which the 365-6 radiation was isolated by Corning glass filter No. 5840 in 2.4 mm thickness, $\times 850$ C From an adult male white rat, after staining with the basic dye Azure A with a method which is specific for chemical staining of nucleic acids Technique Fixed in acetic alcohol (1:3), embedded in paraffin, and sectioned at 5μ , stained as described in (12), photographed on Kodak M plates, using a tungsten ribbon filament lamp and a Bausch and Lomb daylight glass filter Magnification $\times 800$ D From the same block of tissue as C, photographed by ultraviolet light to show the high absorption in regions of nucleic acid concentration Technique Sectioned at 3μ and mounted on a fused quartz slide, paraffin removed with chloroform, and section mounted in glycerin saturated with chloral hydrate, as recommended by Kohler (13), photographed on Kodak Process plates, at $254m\mu$, with the apparatus described by Pollister and Moses (14), using a Cooke, Troughton, and Sims 81 \times monochromatic objective, $\times 800$ E Adjacent section to C, which has been digested with ribonuclease before staining with Azure A Technique Digestion for 2 hrs at $37^\circ C$ with Worthington's crystalline ribonuclease, concentration 0.2 mg/ml pH 6.0, boiled before use with saturated $(NH_4)_2SO_4$ to destroy protease activity, staining, photography, and magnification as in C F An adjacent section to C, after the Feulgen reaction for desoxyribose Technique Feulgen reaction as described in (12), photographed as in C, using a Wratten 58 filter instead of the daylight glass

tein is the basis of the staining of cytoplasm with acid dyes, like eosin. A more satisfactory chemical method of showing intracellular distribution of protein is by use of a protein test, like the Millon reaction, which is specific for tyrosine and tryptophane. As figure 2B shows, there is protein throughout all parts of the cell, with especially conspicuous concentrations in the zymogen granules and the nucleolus. Such a photomicrograph as this has no chemical meaning unless it can be shown that the method is specific for protein. It is a major distinction between the attitude of many cytologists of the past and of those of today that this point is always critically examined. That the Millon color on slides is formed with the reactive protein groups is demonstrated by the fact that protein masses which are known to be deficient in tyrosine and tryptophane, such as collagen and protamine, are Millon-negative on slides in which adjacent proteins are strongly positive.

The old method which demonstrates the intracellular distribution of nucleic acid is by staining with an acid solution of a basic dye, such as Azure A, shown in figure 2C. Histologists call this basophilia. There is strong stain in the chromatin and nucleolus of the nucleus, and in the broad basal part of the cytoplasm. The last reaction has been known for a long time, and a special name, *ergastoplasm*, was given to it before the chemical basis of the staining reaction was understood. Strictly speaking there are two sorts of strongly acid basophilic substances in cells, the phosphoric acid esters which include the two nucleic acids and the sulphuric acid esters which include such substances as mucopolysaccharides. The latter are relatively rare and easily distinguished from nucleic acid when they are present. For precise characterization of the basophilic material in any part of the cell further cytological tests are always necessary. For example, after a companion slide to the last has been digested by ribonuclease the basal zone and nucleolus are no longer stainable with Azure A, while the chromatin still stains as heavily as in an undigested slide (fig 2E). If the ribonuclease digestion is followed by desoxyribonuclease, then the slide will not stain at all with Azure A.²

² It should be pointed out that it is dye-binding capacity which the Azure A staining indicates. This property depends to a certain extent, perhaps variable from tissue to tissue, upon the association of the nucleic acid with protein, hence a weak or negative basophilia does not necessarily always indicate a low concentration of nucleic acid.

That the nucleic acid of chromatin is largely if not entirely of the desoxypentose type is confirmed by the highly specific Feulgen reaction for this sugar. With this method, as with the azure stain after ribonuclease, there is only a nuclear pattern to indicate the cellular structure of the pancreas (fig 2F). As would be expected, after predigestion of a slide with desoxyribonuclease the Feulgen reaction is negative.

In addition to the basophilia due to phosphoric acid groups of nucleic acid and the Feulgen reaction of the desoxy-sugar the strong natural absorption of the purine and pyrimidine bases has proved to be, in Caspersson's hands, a useful method of localization of polynucleotides. Figure 2D, which is a companion slide to that from which 2C was photographed, clearly shows, as did the basophilia, the nucleic acid localization in the chromatin, nucleoli and basal zone of ergastoplasm. The method of Caspersson (17) has been to measure complete ultraviolet absorption curves of points in different parts of the cell, and from the curve shape to draw conclusions about the approximate nucleoprotein composition. For example, the basal zone shows a nucleic acid curve with distortion of the long wavelength slope due to the protein, while a region of the zymogenic granules shows only protein ultraviolet absorption. As with basophilia, it has been shown (e.g. by Davidson, 17a) that nuclease digestion reduces specifically the ultraviolet absorption of areas like either the basal zone and nucleolus or of the chromatin, while absorption in all these regions is reduced by pretreatment of the section with both enzymes, or with hot trichloroacetic acid. Unlike basophilia, the ultraviolet light loss is by no means all due to specific nucleic acid absorption, a certain amount at any wavelength is due to protein absorption, and often as much as half of the light loss is non-specific because of scattering and internal reflections in the dense protein mass (1, 17).

The variety of techniques which may be used to localize nucleic acids within the cell may be briefly summarized. Both pentose and desoxypentose nucleic acid are basophilic, absorb ultraviolet light strongly, and are soluble in hot trichloroacetic acid, the specificity of the nucleases and the Feulgen reaction serve to demonstrate whether the nucleic acid in a given region is predominantly of the pentose or the desoxypentose type.

Application of these nucleoprotein methods has completely clarified the questions of distribution

of nucleic acids in cells. Independently Caspersen and his fellow-workers, using ultraviolet absorption and the Feulgen reaction, and Brachet and his associates (19), using bisophila, ribonuclease, and the Feulgen reaction, have made it clear that a) chromatin is the site of major intracellular concentration of deoxyribose nucleic acid, b) ribose nucleic acids are especially characteristic of the cytoplasm and the nucleolus, and c) that there are striking changes in amount of ribose nucleic acid in cells in which protein synthesis is especially rapid, as in growth or synthesis of a glandular product. The cell shown above had completed synthesis of a batch of granules, if this were about to begin it would have been noted that the basophilic ergastoplasm would have been much increased, extending distally into the region level with the nucleus.

The qualitative cytological methods which have just been discussed lead to localization of a substance within a cell by its absorption, which is detectable visually. Cytologists usually speak of the intensity of a stain or color reaction as weak, strong, very dark, etc.—and, of course, these terms imply semi-quantitative evaluation of the concentration of the component which is responsible for the color. When two objects are side by side in an evenly illuminated microscopic field, or in the two fields of a comparison eyepiece, visual matching appears to be as accurate as objective photometric measurements. With objects of the same size, proper visual comparison is then a rough indication of relative amounts, if two objects are equally dark they may be assumed to have approximately the same amount, and if they appear different the darker one may be taken to contain more reacting substance. The same conclusions regarding relative concentrations may be drawn of two bodies of equal vertical thickness (equal absorbing path). More often, the quantitative question which faces a cytologist cannot be answered even roughly by visual comparison. For example, one often wishes to know relative amounts in two objects of very different size. It is uncertain to what extent by visual study a microscopist can even determine whether two such unequal objects have the same intensity (a rare condition probably), for the relative sizes of the contrasting surroundings introduce considerable difficulty. If this match could be accurately made, then from the dimensions of the object one could compute a fairly good estimate of how much more substance the larger object contained.

The above examples illustrate the range of visual microscopic comparison. If, to cite a very common experience, one cytological object is larger and more lightly colored than another, the cytologist is almost completely helpless to answer the obvious question of whether the decrease of color is entirely due to dilution in the larger mass. The relation of volume to light absorption is easily computed from an actual figure, a measurement of extinction, but such a quantitative datum is absolutely necessary. No amount of experience can train a cytologist's eye to operate as an objective microscopic photometric device. These measurements must be made with objective photometers.

Fig 3 DIAGRAM of a simplified apparatus for photometric measurements of cytological preparations. After Swift (20)

At the Columbia Laboratory we have for some time been exploring the possibilities of escape from these limitations of visual estimation by adapting quantitative photometric analysis to cytology. We hoped to be able to substitute objective relative values for the differences in absorption which the eye or a photographic plate detects as different intensities. The photometry can be made by carefully controlled photography and densitometry, but it is easier and more accurate to measure the absorption directly by a phototube mounted in the optical axis directly above the microscope (fig 3). Measurements are made at a single wavelength, near the absorption maximum.

If methods of demonstration of nucleoprotein are to be used in this quantitative fashion ob-

viously they must, in addition to being specific, be reproducible to a known extent. For example, the staining technique must be standardized so that it comes to a sort of end point, always reaching approximately the same intensity with a given sort of cytological material. When I started to measure cell structures it at once became apparent that the individual absorption measurements on any object within a single section were variable over a considerable range—a situation which has likewise been found by all other workers who have given attention to the question. The data for any one object group themselves into

that from cell counts (table 1) Boivin and the Vendrelys (7) concluded that the nuclei of tissue cells of any one species of animal all contained approximately the same average amount of DNA. This was fully confirmed by Swift's (20) photometric measurements of individual nuclei of 11 different tissues of the rat (table 3). Essentially similar results have been reported by Pasteels and Lison (23) and by Leuchtenberger, Vendrely and Vendrely (24). It does indeed appear that specializations of cells do not involve major changes in amount of desoxyribose nucleic acid.³ Swift's photometric measurements also confirmed

Mean extinction values and standard errors of the mean Feulgen stained erythroblast nuclei, smears of human marrow, all nuclei 9.5 μ in diameter. The extinction, E_{440} , is a measure of the amount of nucleic acid in the nuclei. From data of Reissner and Korson, 1951 (22).

fairly normal looking unimodal distribution curves (21). Reproducibility of one of these cytochemical methods must therefore always be estimated by statistical analysis. The shapes of the distribution curves are the same from slide to slide, but reproducibility is more easily assessed by comparing mean values for each population measured. The methods now in use in our laboratory show means which are reproducible within about 10 per cent of the total extinction, as shown for example in Reissner and Korson's data (22) on the Feulgen reaction in human erythroblasts (table 2). Using this simple statistical method of studying slides, a change of composition is detected as a significant difference in mean value.

The results with this quantitative cytology have been most striking when applied to the cell nucleus, especially in measuring its content of desoxypentose nucleic acid. It will be recalled

the view of the constant relationship of DNA to number of sets of chromosomes and strengthened the validity of it by showing that polyploid nuclei with 4 and 8 sets of chromosomes had a corresponding greater amount of desoxyribose nucleic acid. Additional cytological researches have traced the synthesis of DNA in animal cells through the cycles of mitosis, meiosis, and fertilization (see Swift, 20, Alfert, 25, Pollister, Swift and Alfert, 19).

These results based upon measurement of the Feulgen reaction not only provide strong con-

³ But it must also be stressed that the cytological values are means of a population in which the highest computed value may be as much as 50% larger than the lowest. Part of this is undoubtedly due to technical difficulties, such as the inhomogeneities of the absorbing mass, but it is quite possible that there is also a considerable actual variation in DNA content from nucleus to nucleus.

firmatory evidence of one major aspect of the significance of desoxyribose nucleic acid in cellular biology but also validate the whole quantitative photometric approach very satisfactorily. If a biochemist is to use a colorimetric method of analysis, an essential calibration procedure is to set up a series of known concentrations, or standards, and to check how accurately his colorimeter readings reflect the known relative concentrations. With cytological photometry this cannot be done. Unquestionably within the cell the nucleoprotein mass is very different, in physical

TABLE 3 DNA CONTENT OF CLASS I NUCLEI OF RAT TISSUES

CELL TYPE	NO OF NUCLEI MEASURED	DNA FEULGEN ARBITRARY UNITS $\left(\frac{E\pi}{F}\right)$
Liver	21	3 34 \pm 0 05
Pancreas	20	3 10 \pm 0 06

After Swift, 1950 (20) In the formula for computing arbitrary relative values, column 3, E is extinction at 550 $m\mu$, r is the radius of the cylinder measured through the center of the nucleus, and F is the fraction of the total nuclear volume which the central cylinder represents

state and in concentration, from that when it is studied *in vitro* after extraction from the cell. This difference must have a profound effect upon not only natural absorption but also upon the course of tests and stains for the protein and nucleic acid. For further discussion of this point consult Pollster, (1). For a cytological calibration which will be comparable with that of an analytical biochemist we must look for a natural condition in which there is a wide range of concentrations. From the averages obtained by cell counts and gross analyses (table 1) it is clear that nuclei of non-dividing tissue cells may present just this desired situation. For, if a mixture of several types of nuclei of widely varying volumes (as in the kidney) show nearly the same average

DNA value as does a population of nuclei which is nearly homogeneous as to size (as in the thymus) then it must be true that in the larger nuclei the DNA has been diluted in proportion to the increase in cell volume. It is as if a biochemist had prepared his samples, not by dilution of one concentration, but by weighing out 10 one-milligram samples and dissolving them in a range of volumes from 1 to a 100 milliliters. The largest diploid nuclei which Swift analyzed cytologically were nearly 20 times the volume of the smallest. Since the computed DNA was approximately alike in the two nuclear types it is evident that the method can satisfactorily estimate relative DNA over a concentration range from 1 to 20⁴.

TABLE 4 NUCLEASE DIGESTION OF DNA IN NUCLEI

CYTOCHEMICAL METHOD	PART OF NUCLEOTIDE MOLECULE MEASURED	PERCENTAGE REDUCTION OF EXTRACTION
Natural UV absorption	Pyrimidine or purine	39 9
Feulgen reaction	Desoxypentose	39 6
Azure A basophilic	Phosphoric acid	37 7

Measurement of the effect of ribonuclease digestion (2 0 mg/ml), at high temperature (56°C), on 5 μ sections of the nuclei of liver cells of the salamander, *Amblystoma*, showing the same reduction of extinction, measured by 3 different cytological photometric methods. (Note such digestion of DNA by ribonuclease is very exceptional, as a rule ribonuclease preparations are highly specific for ribonucleic acid.)

A careful analytical chemist often checks his results with one method by comparison with others. This is readily done with the variety of techniques for estimation of DNA by cytological photometric analysis. Table 4 shows that when there was about 40 per cent reduction of the extinction of the Feulgen reaction, in this experiment with ribonuclease at high temperature, this

⁴ The average amount per diploid rat nucleus has been given from cell counts as 5.5×10^{-3} mg (Leuchtenberger, Vendrely, and Vendrely, 24). From this it may be computed that the average concentration within the normoblast nucleus (volume 24 μ^3 , after Swift) was of the order of 2.3×10^{-10} mg μ^3 (23%), and that within the nucleus of the motor neurone (volume, 460 μ^3) the DNA concentration was 1.2×10^{-11} mg μ^3 (1.2%). By contrast, about the highest concentration of DNA which is readily measurable by ultraviolet absorption in a cuvette one centimeter thick is less than 0.01%.

loss of DNA was also independently determinable by measuring either the capacity of the phosphoric acid to bind Azure A, or the natural ultraviolet absorption

The results which I have just been discussing were all expressed in arbitrary units, either extinctions or values computed from the extinctions, taking into account the geometry of the object measured. If the relation of the intensity of the reaction measured to the absolute amount of substance were known, from the extinctions the absolute amounts could have been readily computed. Very early in this work Ris and I (26) published what appeared to be this sort of validation of ultraviolet absorption measurements of individual nuclei—but this now appears to have been no more than the result of a fortuitous combination of errors. From the results of Swift and others it is apparent that in rat tissues, the Feulgen reaction bears a constant relationship to the DNA content, but it is not known to what extent this relationship holds from species to species. It is obvious, of course, that of itself the absolute amount in a given cell or cell component is of limited importance, most of the problems can be adequately solved if relative values can be determined.

The work on the desoxyribose nucleic acid content of animal nuclei has combined biochemical and cytological approaches to give a picture of this component of the nucleus as fairly constant, markedly altered only when the chromosome number is changed or the material for new nuclei is synthesized. A similar interdependence of the two approaches is leading toward clarification of the problem of the total nucleoprotein composition of nuclei (27). The older analytical data indicated that even in liver nuclei the protein content was not more than two or three times that of nucleic acid. The available cytological data, by contrast, showed indications that the protein content was much higher, up to 5 to 20 times the nucleic acid. Leuchtenberger and I

assumed that this meant that the washing incidental to the isolation of nuclei removed a considerable amount of the protein, and we showed by photometric measurements of nuclei in fresh slices of liver that such loss did indeed occur. From other analytical data, most of them more recent, and using different isolation procedures there may be computed considerably higher protein values which are in some cases (28) even higher than those we gave for liver. We now know that our ratios were probably high by a factor of two, but even with this correction the protein content is much higher than that from the older analyses. From the gross analytical data alone it could not be decided whether the low values were a result of loss of protein, or whether the high values indicated that protein had been adsorbed onto the nuclei from the surrounding cytoplasm. The comparison of the cytological and biochemical data, however, makes it highly likely that the nucleus does, as a rule, contain high protein concentration, quite comparable with that of the cytoplasm.

In closing, I should like to summarize briefly. The attempt to localize substances in cells is one approach to the broad problem of determining to what extent cellular structure reflects diversity in distribution of the physiological functions of the cell. Localization of substances can best be achieved by a combination of two approaches, analysis of isolated masses of cell components and direct localization by microscopic study of cells. In most cases the cytological study must be made on fixed cells, on which a variety of specific tests, stains, digestions, and chemical extractions can be carried out. Cytological localization methods are best developed for proteins and nucleic acids, and these have been adapted to yield quantitative estimations of relative amounts in cells. The quantitative techniques have been used most successfully in study of the composition of the cell nucleus.

SEPARATION AND PROPERTIES OF CELL COMPONENTS¹

GEORGE H. HOGEBOM

From the National Cancer Institute, National Institutes of Health,² Bethesda, Maryland

CERTAINLY the most versatile approach to an understanding of the relation between cell structure and cell chemistry is the procedure of cell fractionation, whereby the cell is mechanically broken and its structural elements are segregated according to size and density by fractionation in the centrifuge. The main advantage of this procedure lies in the fact that cell fractions can be obtained in sufficient amounts to permit the direct application of quantitative biochemical methods of analysis as fast as these methods are developed. To the best of my knowledge, no other general cytochemical technique has this capability.

It is, therefore, simple enough to prepare a broken cell suspension, subject the suspension to increasing centrifugal force, isolate particles of various sizes, and carry out chemical analyses on the fractions obtained. Past experience has amply demonstrated, however, that it is not simple to arrive at firm conclusions relating the chemical data to the structural make-up of the cell, and this is the point where the cell fractionation procedure must be examined critically. Now what is liable to happen when the cell membrane is broken? First, the intracellular structures are dispersed into an aqueous medium bearing only a faint resemblance to that within the living cell. When so dispersed, the structural elements behave appropriately by displaying a pronounced tendency to undergo morphological alteration. (1) Aside from the fact that this phenomenon of morphological alteration can make it difficult if not impossible to identify cytologically the dispersed structures and thus to determine the composition of isolated cell fractions, a number

of other undesirable phenomena might be expected to follow, such as a redistribution of biochemical properties as a result of leakage of substances through damaged membranes, or adsorption of soluble compounds on particulate material.

These considerations have led to the establishment of several criteria defining an adequate isolation procedure, the first and most obvious of which is that a sound cytological background must be provided. Thus the morphological integrity of the cell structures must be preserved to such an extent that the composition of the isolated fractions can be directly determined by cytological study. It seems reasonable to believe that this principle also has some bearing on the possible occurrence of redistribution of biochemical properties after cell disruption. Thus the membrane of a cytologically intact structure, for example nucleus or mitochondrion, would probably be less likely to leak than the membrane of an obviously altered structure.

A second item of importance involves the question of yield. To isolate only a small proportion of the nuclei or mitochondria of a given tissue and attempt to interpret results obtained with that preparation in terms of the whole tissue is an extrapolation of questionable validity, particularly when one considers the possibility of heterogeneity of cells and perhaps even of nuclei or of mitochondria. It is therefore necessary to provide a means by which almost all of the cells of a tissue can be broken and to devise a fractionation procedure permitting reasonably clean separation of the various cell components and their isolation in good yield.

Two important additional points arise in connection with the biochemical analysis of the fractions and the interpretation of the biochemical data. First, it is essential to analyze both the original whole tissue and all the fractions obtained from it. By this means it is possible to draw up a balance sheet, which serves as a test of the validity of the analytical method, enabling one to detect the presence of inhibitors or activators or the possible role of more than one cell

¹ For the sake of brevity, the following abbreviations will be employed: DPN = diphosphopyridine nucleotide, TPN = triphosphopyridine nucleotide, ATP = adenosine triphosphate, ATPase = adenosine triphosphatase, AMP = adenosine-5-phosphate, AMPase = AMP phosphatase, DNA = deoxyribonucleic acid, PNA = pentonucleic acid.

² Federal Security Agency, U. S. Public Health Service.

component in a given biochemical reaction. The second requirement arises from a consideration of the possibility of adsorption of soluble compounds on particulate material and of an overlapping of fractions that may not be readily detected by cytological study. Thus in an investigation of the distribution of an enzyme among cell fractions, the presence in a single fraction of a relatively small proportion of the total enzyme should be interpreted with caution. The finding that the enzyme is concentrated in the fraction to a greater extent than in the original whole tissue is much more likely to be significant from the cytochemical standpoint.

Up to the present time, mammalian liver has been by far the most popular tissue for cell fractionation studies. Liver presents certain definite advantages over most other tissues. It is largely composed of what appears to be a single cell type and the individual liver cells are large and easily disrupted. The abundant cytoplasm contains many mitochondria (probably somewhere in the neighborhood of 700³ per cell), and apparently several types of submicroscopic structures which have recently been revealed by electron microscopy. Also present in the cytoplasm and visible in the light microscope are lipid droplets and a number of small spherical secretory granules which stain with neutral red and are usually located near the periphery of the cell. The cell contains a single nucleus containing 1 to 3 nucleoli.

By utilizing the mitochondrion as a test object, it has been possible to obtain a considerable amount of information concerning the proper conditions for fractionating the liver cell. The mitochondrion, which has almost as widespread a distribution among cells, plant and animal, as the nucleus, has certain characteristic cytological properties, including a usually elongated shape, the probable presence of a surface membrane, specific staining vitally with Janus Green B and after special types of fixation with certain other dyes, and a very pronounced sensitivity to mishandling. In the latter respect, both the cytological and biochemical properties of mitochondria are markedly affected by the composition of the suspending medium. The following facts became apparent in a study of the effect of various media on mitochondria (1). The use of

water or other hypotonic solutions causes prohibitive morphological alteration, and the use of solutions of electrolytes at the isotonic level produces aggregation of the particles to such an extent that they cannot be adequately separated from nuclei. An answer to these problems of morphological alteration and of aggregation was found, however, in the use of solutions of non-electrolytes. Two media evolved from the study: isotonic (0.25M) sucrose in which the mitochondria change from an elongated into a spherical shape but otherwise retain their normal cytological properties, and hypertonic (0.88M) sucrose in which the particles retain both their normal shape and staining properties. Subsequently, a comparative study of these two media has led to the conclusion that neither possesses any distinct advantage as far as the distribution of biochemical properties among the cell fractions is concerned. There are, however, difficulties associated with the use of hypertonic sucrose, including the necessary addition of large amounts of sucrose to reaction mixtures and, because of the high density and viscosity of the solution, a requirement for high centrifugal forces in the fractionation procedure. For these reasons we are at present using the more convenient of the two media, namely the isotonic sucrose. Perhaps I should point out, however, that we do not by any means feel that the choice of a proper medium for cell fractionation is a closed problem. Sucrose solutions are certainly far from physiological in the sense of duplicating the medium of the cytoplasm, and we are well aware of the possibility that artifacts may eventually be encountered as a result of the use of such unphysiologic solutions. The addition of various salts at low concentrations to the sucrose solutions in an attempt to improve the physiological characteristics of the media has, in our experience, invariably resulted in some degree of aggregation of particles and thus in difficulties in obtaining adequate fractionation.

The fractionation procedure (2) is, of course, carried out entirely in the cold, the temperature of the preparations being maintained at 5° or less. In our experience, the Potter-Elvehjem homogenizer (3) provides the most satisfactory method for disrupting cells, since its use results in the breakage of 80 per cent or more of the liver cells without damage to an appreciable proportion of the nuclei. The Waring blender is entirely unsatisfactory for the preparation of

³ This value was obtained by making simultaneous counts of nuclei and mitochondria in homogenates of mouse and rat liver.

homogenates suitable for cell fractionation studies. The subsection of liver, for example, to the action of the Waring blender for periods sufficient to disrupt most of the cells results in the breakage of many nuclei and even of some mitochondria.

By the use of increasing centrifugal forces, four fractions are obtained from homogenates of mammalian liver, first, a nuclear fraction containing about 15 per cent of the original total nitrogen and including all of the nuclei of the homogenate together with some residual intact cells and a variable but usually small number of free mitochondria, second, a mitochondrial fraction in which virtually all of the visible particles satisfy the cytological criteria for the identification of mitochondria and in which, as indicated by electron microscopy, there are apparently few submicroscopic particles (1). The mitochondrial fraction contains approximately 25 per cent of the original total nitrogen. The third fraction, the submicroscopic particles or microsomes, contains 20 to 25 per cent of the original nitrogen. The types of structures present in this fraction have not as yet been clearly defined, although recent studies carried out with A. J. Dalton with the electron microscope have indicated the presence of several types of particles of diameters ranging between 30 and approximately 150 millimicrons. The fourth fraction, a final supernatant, contains 35 to 40 per cent of the original nitrogen and is made up of the soluble material of the cell, possibly some very small particles, lipid droplets, and some of the secretory granules. It is our experience that most of the secretory granules do not exist as formed elements after disruption of the liver cell (1).

It is apparent, therefore, that this fractionation procedure is suitable for the isolation of the structural elements of the cytoplasm but does not yield a homogeneous preparation of nuclei. In fact, it seems unlikely that a satisfactory method for the isolation of cytologically intact nuclei in good yield has yet been developed. Although the use of the citric acid method, for example, permits reasonably clean separation of nuclei from cytoplasmic constituents, the nuclei so obtained are obviously morphologically altered (4). A similar picture is obtained by the use of the Behrens' procedure (5, 6). Recently, several modifications of the sucrose (7, 8) technique have yielded clean preparations of nuclei that appear cytologically intact, but all these

methods thus far permit the isolation of only a small proportion of the total number of nuclei of the tissue.

By far the most striking result of studies of the biochemical properties of cell fractions has been the partial elucidation, by work carried out in a number of laboratories, of the important role played by mitochondria in the metabolism of the liver cell. In this respect, one of the earliest discovered enzymatic properties of mitochondria was their content of cytochrome oxidase and succinic dehydrogenase (9, 10). Several experiments have suggested that these two enzyme systems are, in fact, exclusively a function of mitochondria, the relatively small amount of activity shown by other fractions probably being the result of contamination by mitochondria (1). Other enzyme systems and related substances that are concentrated in this fraction of liver are ovalacetic acid oxidase (11), octanoic acid oxidase (12, 13), glutamic dehydrogenase,⁴ DPN cytochrome reductase, TPN cytochrome reductase (14-16), adenosinetriphosphatase (9, 17), catalase (18), uricase (19), cytochrome *c* (2, 20), riboflavin (21), and vitamin B₆ (22). The system catalyzing the synthesis of *p*-aminohippuric acid from *p*-aminobenzoic acid and glycine was largely recovered in the mitochondrial fraction (23). Recently, Kielley and Kielley (24) in an interesting study of oxidative phosphorylation have shown that in the presence of an oxidizable substrate, such as α -ketoglutarate, liver mitochondria are capable of synthesizing ATP from AMP and inorganic phosphate at a very rapid rate, the net uptake of inorganic phosphorus at 28° being approximately 2 μ M/min/mg of mitochondrial nitrogen. In this study it was also shown that the 'myokinase' activity of liver is largely, if not exclusively, associated with mitochondria and plays a prominent role in the phosphorylation mechanism (24). The adenosinetriphosphatase (ATPase) of mitochondria was found to be non-operative under the conditions of ATP synthesis and became operative only when the particles were aged or subjected to procedures causing structural alteration and at the same time a loss of their ability to carry out the phosphorylation reaction. The latter finding brings up the interesting possibility that ATPase may under appropriate conditions actually function as a synthesizing system.

⁴ Hogeboom, G. H. and W. C. Schneider. Unpublished experiments.

Of the enzyme systems that are concentrated in mitochondria, several are apparently not exclusively associated with this cellular element. The cytochrome reductases, for example, are also concentrated in microsomes. ATPase is also concentrated in the nuclear fraction, catalase and cytochrome *c* in the final supernatant, and the activity of mitochondria in the oxidation of oxalacetate, and to a lesser extent of octanoate, is enhanced by the addition of other fractions which by themselves are inactive. The situation with respect to α -ketoglutarate oxidation is not entirely clear, since a satisfactory method for the assay of this system in homogenates is not available. Isolated mitochondria, however, are capable of oxidizing α -ketoglutarate in the presence of AMP and magnesium ions at a reasonably rapid rate, the Q_{O_2} in terms of milligrams of total nitrogen at 28° being approximately 400 μ l of O_2 /hour (24). It thus seems possible that mitochondria are largely responsible for this reaction.

Another interesting study having a bearing, from the negative standpoint, on the properties of mitochondria, was carried out by LePage and Schneider (25). These investigators found that over 50 per cent of the anaerobic glycolytic activity of rabbit liver was recovered in the final supernatant. No other fraction showed appreciable activity except the nuclei, which, of course, were contaminated by intact cells. When the fractions were recombined, the activity of the supernatant was enhanced greatly by the addition of microsomes but only slightly by the addition of mitochondria. It would thus appear that mitochondria are not intimately concerned with the anaerobic phases of glycolysis.

Another finding of interest from the negative point of view is that mitochondria contain only a relatively small amount of pentose nucleic acid (1, 9, 17). Approximately 25 per cent of the total mass of mitochondria appears to be composed of lipide, of which about two-thirds is phospholipide (26-28).

It seems apparent, therefore, that mitochondria are chiefly concerned with the oxidative metabolism of the cell, including some of the reactions of the Krebs cycle. Perhaps their most interesting biochemical property, arising from the studies on phosphorylation, among others, is their ability to carry out reactions capable of supplying energy for synthesis.

As far as the enzymatic properties of the nucleus are concerned, the results of investiga-

tions of the nuclear fraction have been largely negative. Although in all cases some enzyme activity is always shown by the nuclear fraction, only in the case of ATPase (9, 17) and AMPase (29) is the concentration of enzyme sufficiently high to rule out contaminating cytoplasmic elements as the cell structures responsible for the activity. In general, the results of enzyme determinations carried out on nuclei isolated by other techniques are open to the same difficulty in interpretation (4). It is, on the other hand, entirely possible that the nucleus actually does contain a large number of enzymes in relatively low concentration, but proof that this is the case is certainly not a simple problem.

The submicroscopic particles or microsomes are characterized by strikingly high concentrations of pentose nucleic acid (PNA) and of lipide, which is mostly in the form of phospholipide. The concentration of PNA in microsomes is some 5 to 6 times that found in the mitochondrial fraction (1, 11, 12, 17, 28), and approximately 40 per cent of the dry weight of microsomes is lipide in nature (26-28, 30).

Until recently, the metabolic function of microsomes has been largely a matter of conjecture, but during the last few years several enzymes have been shown to occur in the fraction in a concentration exceeding that in whole tissue. These enzymes include both DPN and TPN cytochrome reductase (14-16), the former being present in considerably higher concentration than the latter. Omachi, Barnum, and Glick (31) have reported that the esterase activity of whole liver is largely recovered in the microsome fraction. Microsomes also play a role in certain other enzyme reactions, including anaerobic glycolysis (25), the oxidation of oxalacetate (11), and the reductive cleavage of *p*-dimethylaminoazobenzene (32).

It is obvious, however, that our present knowledge of the role of microsomes in cellular metabolism is quite limited and does not permit the type of generalizations that can be made in the case of mitochondria.

The fourth fraction obtained from mammalian liver, the supernatant, is, of course, a highly complex mixture containing all of the enzymes involved in anaerobic glycolysis (25), as well as isocitric dehydrogenase (16), acid and alkaline phosphatase (29), catalase (18), cytochrome *c* (20), and undoubtedly many other substances of biochemical importance. A detailed study of the types of proteins present in the soluble frac-

tion of the cell is a problem of major proportions in itself. Recently, some steps in this direction have been made by Sorof and Cohen through the use of electrophoretic and ultracentrifugal analysis (33, 34).

Perhaps it would be of some interest if I were to devote the last few minutes to a discussion of recent experiments designed to investigate further the properties of liver mitochondria. For a time it was somewhat disturbing to find that practically all of the enzyme systems associated with mitochondria were 'insoluble', i.e. easily sedimented from extracts of practically any tissue, not obtainable in a monodisperse state in true solution, and thus refractive to extensive purification. Notable examples were cytochrome oxidase, succinic dehydrogenase, ATPase, and DPN-cytochrome reductase. In view of evidence favoring the existence of a mitochondrial membrane (35, 36) and in spite of the cytological evidence for the integrity of isolated mitochondria, it seemed conceivable that the membranes of the particles were actually being damaged sufficiently during the fractionation procedure to allow the escape of soluble substances, leaving only an insoluble residue. Several lines of evidence have clearly indicated, however, that this is not the case. More recent studies have shown, for example, that several soluble proteins that can readily be purified, such as cytochrome *c*, TPN-cytochrome reductase, myokinase, and glutamic dehydrogenase, are concentrated to a considerable extent in the mitochondrial fraction. Finally, when the mitochondrial membranes are mechanically broken (37, 38) either by the use of intense sonic vibrations or by forcing the particles through a small orifice under high pressure, approximately 60 per cent of the total nitrogen is released into solution. Further studies of the soluble fraction of mitochondria have shown that it consists largely of proteins that can be separated and characterized in the analytical centrifuge. Different refractive index patterns are obtained by the two methods of disintegration of mitochondria, the only component that appears to sediment as a monodisperse system being released by sonic vibrations (38). This component which constitutes a large proportion of the total protein of mitochondria, and is characterized by

a sedimentation constant of 6.2 Svedberg units, is apparently either denatured or dissociated when the mitochondrial disintegration is carried out by forcing the particles through a small orifice.

Of some interest is the fact that the soluble fraction of mitochondria isolated from a liver tumor shows a qualitatively different protein pattern in the analytical centrifuge, in that the main component obtained from normal liver mitochondria appears to be absent (38), whereas other components are seen that correspond in sedimentation constant to those of the normal liver mitochondria. Furthermore, the two methods of disintegration produce identical patterns in the case of the tumor mitochondria but strikingly different patterns in the case of normal liver mitochondria. Attempts are now under way to isolate and characterize the component of normal liver mitochondria that cannot be detected in the tumor preparation.

The effect of the disintegration of mitochondria on the enzyme systems of the fraction is also of some interest. Myokinase and glutamic dehydrogenase are released into solution. Cytochrome oxidase, DPN-cytochrome reductase, ATPase, and, somewhat surprisingly, cytochrome *c* remain attached to particles that are sedimented with considerable difficulty, not being completely sedimented by 30 to 40 minutes centrifugation in an angle centrifuge at 150,000 *g*. Moreover, the specific cytochrome oxidase and DPN cytochrome reductase activities of the slowly sedimenting particles are much higher than the corresponding activities of the original preparation of mitochondria. It is obvious that without the availability of a high speed centrifuge permitting sedimentation with a minimum of convection, it could be erroneously assumed that these 'insoluble' enzymes had been brought into solution.

As I have attempted to illustrate, the procedure of cell fractionation, despite certain deficiencies, is capable of yielding a considerable amount of information both in the field of cytochemistry and in basic studies of the mechanism of biochemical reactions. It is our hope that future efforts in this field will emphasize the development of new methods capable of checking independently and extending the present data.

INTRACELLULAR ENZYME DISTRIBUTION, INTERPRETATIONS AND SIGNIFICANCE¹

VAN R. POTTER, R. O. RECKNAGEL AND R. B. HURLBERT

From the the McArdle Memorial Laboratory, The Medical School, University of Wisconsin, Madison, Wisconsin

It is now 9 years since the symposium entitled "Frontiers in Cytochemistry" was held in honor of Prof. R. R. Bensley at the University of Chicago and what little we know about enzyme distribution in cells has developed largely since that time, inasmuch as almost no data on intracellular distribution of enzymes were presented at that meeting. Indeed, the first observations on succinoylase distribution as reported there differ considerably from present views. Nevertheless a beginning was made and the time was ripe for further developments.

A recent review by Schneider and Hogeboom (1) has surveyed the literature on enzyme distribution up to this time, and therefore in covering the subject that was assigned to me for the present occasion, I shall feel free to spend more time on what we take to be the significance of studies in this field rather than to cover such details of enzyme localization as are available. Since this field is just beginning to establish itself, this may be a good time to take stock of our present position and to ask ourselves what we may hope to accomplish by these studies.

There are two approaches that are beginning to be widely applied in the field of intracellular enzyme localization. One is the so-called histochemical method, based on the classical methods of histology, and the other is the method that is based on the early experiments by Bensley and by Claude, namely, the method of differential centrifugation of homogenized tissue samples. We shall not attempt to interpret the findings obtained by the histochemical method except in one instance, in which the application by Novikoff (2, 3) of the method of differential centrifuga-

tion to the localization of alkaline phosphatase led directly to the rejection of the widely held view that the enzyme was localized in the nucleus, as indicated by the usual histochemical method. The same view has now been accepted by Gomori (4) and is apparently not a subject of controversy.

The early philosophy of the differential centrifugation school was summed up very neatly by Professor Bensley in the statements that "It would seem to be an axiom of analytic chemistry to separate separable things before proceeding to their analysis," and "The analysis of particulate components of cytoplasm is only as good as the species purity of the preparation" (5). Although it is apparent that Bensley regarded the immediate task as analytical, he was also well aware of the broader implications of the work. He said, "Obviously the possibility of separating mitochondria and particulates, and of isolating the structural proteins for chemical study, opens a rich field for further research. The localization of enzyme and carrier systems, vitamins and hormones, and the viruses, functional changes in composition, the tracing of radioactive isotopes into the interior of the cell, and the further fractionation of the submicroscopic particles by more refined methods all offer inviting opportunities to the inquiring mind" (5). It is the purpose of the present discussion to inquire whether the hopes and predictions of Bensley were justified, in the light of the subsequent 9 years of experimentation in this field. What are some of the objectives that we may hope to attain by further work in this field?

OBJECTIVES

When looked at as an analytical problem, that is, the determination of enzyme distribution in the obtainable cell fractions, it must be realized that anything less than the quantitative approach has very little significance. Thus the problem of enzyme distribution in cell fractions involves the same hazards and the same precautions that are

¹The experimental work from the authors' laboratory was supported in part by grants from the National Cancer Institute of the National Institutes of Health, Public Health Service, and from the American Cancer Society on the recommendation of the Committee on Growth of the National Research Council.

met in applying the homogenate techniques to the determination of enzymes in tissues as pointed out in 1944 (6). This means that the reaction mixture must be fortified with such cofactors and adjuvants as may be required to make the given enzyme the rate determining factor. But it must be clear that the enzyme distribution studies are not an end in themselves. It is clear by this time that the localization of enzymes in cell fractions is no longer the main line of development in this field but that the methods of differential centrifugation can now be used as a powerful tool for the study of *intracellular physiology*, which is the underlying basis of physiology at all higher levels.

What can we hope to gain by knowing more about where the individual enzymes in a cell are located? Stated in the broadest terms, these studies have as their objective the understanding of events occurring at higher levels of organization.

In order to understand these events it is necessary to effect a fusion between the morphological or structural aspects of biology and the chemical or metabolic aspects, and to correlate both along the time scale. The understanding of the morphological and metabolic changes at various levels of organization is in our opinion *primarily a matter of understanding the control or regulatory mechanisms that are called upon*. In this connection, we think of enzyme action in terms of two main categories: 1) the *controlled enzyme activity* that is manifest *in situ* at the highest level of enzyme organization, namely, the intact animal, in which the manifold factors of the internal and external environment are brought to bear, and 2) the *potential enzyme activity* that the various enzyme systems can be shown to possess at lower levels of organization, such as the homogenate or the cell fraction. In this discussion we hope to show how the methods of differential centrifugation of homogenized tissues can contribute effectively to studies at both levels, and to mention various subsidiary problems that arise.

CONTROLLED ENZYME ACTIVITY IN SITU

An example of how these methods are proving useful for the study of controlled enzyme activity *in situ* lies in the field of nucleic acid metabolism. For some time evidence has been accumulating in the laboratory of Caspersson (7) and elsewhere that important interactions between the nucleus and cytoplasm are involved in nucleic acid synthesis. The studies based on microscopic

examination of individual cells have certain limitations for the study of metabolic processes, and various investigators, including Jeener and Szafarz (8), Barnum and Huseby (9) and Marshak (10) have attempted to supplement the findings on single cells with metabolic studies involving isotopic phosphorus combined with techniques of differential centrifugation. Their studies were complicated by the fact that phosphorus can follow many metabolic pathways, but nevertheless valid conclusions were reached as to the high metabolic activity of the nuclear PNA (pentose-nucleic acid). I will illustrate this type of experiment with data that are being obtained in

Fig 1 SPECIFIC ACTIVITY of PNA in rat liver cell fractions

our laboratory by Mr Huilbert. We injected rats with 1 mg of C^{14} labeled orotic acid (11), which has been shown to be converted into the pyrimidines of nucleic acids in high yield (12-15), while the purines do not incorporate this substance. Rats were killed at time intervals of 2, 4, 8, 12, 20 and 91 hours and the amounts of radioactivity in the internal organs, respiratory CO_2 and excretory products were determined. The livers contained most of the C^{14} retained in the body. They were homogenized and separated into nuclear, mitochondrial, and supernatant (S_2) fractions by differential centrifugation using the sucrose medium as employed by Price, Miller and Miller (16). The PNA and DNA of the nuclear fraction were separated. In the initial period, most of the C^{14} was in the nuclear fraction and was in the pentosenucleic acid (PNA) of this fraction. No C^{14} was detected in the desoxypentose nucleic acid (DNA) at this time. The results (fig 1) are shown in terms of the specific activities of the PNA of the nuclear, mitochondrial and supernatant (S_2) fractions. From this first approximation of the intracellular distribu-

tion it is clear that the label was first incorporated into the PNA of the nuclear fraction, then into the PNA of the cytoplasmic fractions. After 91 hours, the DNA had attained only a small fraction of the radioactivity in the liver. Thus the suggestions of earlier workers regarding the importance of the nuclear PNA (7-10), considered to reside largely in the nucleolus, is reinforced by these studies, more particularly because instead of using P^{32} the present study was carried out with orotic acid. This substance is incorporated with a comparatively high yield, and has alternative metabolic pathways that appear to be more restricted than those of phosphorus. From these data it is clear that the orotic acid is not being taken up at the same rate by all parts of the cell—it is being taken up by the nucleus, and indeed by a specific portion of the nucleus other than the DNA portion. By following the rates of incorporation of the label from orotic acid into the various cytoplasmic particles along the time scale, and under various conditions which augment the incorporation into the DNA of the chromosomes, it should be possible to test some of the current hypotheses regarding the origin and interrelationships among the various formed bodies found within the cell (cf. 8).

We feel that these data illustrate how the method of differential centrifugation combined with appropriate isotopic precursors can be a powerful tool for the study of the controlled activity of localized enzymes *in situ*, operating at the highest level of enzyme organization. This was the first main category of enzyme activity which we mentioned as an important field for the application of these methods to the problem of the control mechanisms.

POTENTIAL ENZYME ACTIVITY

The second main category in which the methods of differential centrifugation seem at present to be indispensable is the study of potential (and experimentally altered) enzyme activity at the lower levels of organization in terms of intracellular control mechanisms. In studying the activity of the cell components we can observe relationships that enable us to begin interpreting the data obtained by means of slices, whole homogenates and the washed residues, etc. It is now clear that many of the enzymes present in the whole organism or even in the tissue slice do not operate at capacity under usual conditions of study. When these enzymes are studied

by the homogenate technique or in isolated cell fractions they will be either *less active* or *more active* than they were *in situ*—less active if the necessary reaction components are in lower concentration than *in situ*, and more active if the reaction components are in optimum concentration. When the enzymes are studied at the level of the homogenate or the cell fractions, it becomes possible to study their requirements for maximum performance while maintaining them in their intracellular form. By learning just what factors are necessary for maximum performance, we are in a position to learn not only the *amount* of the enzyme present in a given cell fraction, but we also learn what factors the other parts of the cell would have to contribute in order to control the activity of the fraction under study. Although there are many ways in which the activity of an enzyme can be regulated (6,17,18), we believe that one of the more important is by the regulation of the supply of substrates and co-substrates (coenzymes), and this is obviously a mechanism in which the spatial distribution of enzymes could be decisive. We refer particularly to the delivery of co-substrates such as inorganic phosphate and phosphate acceptors, which appear to be necessary components and hence common denominators in a large number of reactions, with the result that any reaction that tends to use up the supply of either of these reaction components can shut off or regulate the rate of all the other reactions that are dependent upon the phosphate balance (6, 19, 20). The delivery of co-substrates can also be decisive in determining the choice between alternative metabolic pathways, as we have recently shown in the case of pyruvate metabolism (21).

Let us examine the data obtainable by various techniques. The first point that needs to be emphasized is that the comparison of slices with homogenates under conditions that are appropriate only for slices is a meaningless gesture. When a reaction can be studied in a homogenate, and the optimum conditions are worked out, the reaction tends to be faster in the homogenate than in the slice. In figure 2 the activity of the homogenate is given as 100 per cent, and the activity of the slice is given as a percentage of the homogenate data. Thus the slices compare with the homogenates as follows: urea formation in rat liver, 43 per cent (22), *p*-amino-hippuric acid synthesis in rat liver, 32 per cent (23), liver oxidation of pyruvate, 38 per cent (24-25), kidney

oxidation of pyruvate, 10 per cent (21, 25), liver synthesis of acetone, 79 per cent (21), and in the case of the only tumor so far studied in these terms, pyruvate oxidation was about equal by both techniques. The possible significance of the latter observation has been discussed elsewhere (26).

It is evident that in many instances the enzymes of the slice are not working at capacity, in comparison with homogenates from the same tissues. Once it is clear that this can be true, it is not too surprising to find reports in which the suppression of an enzyme *in vivo* is so pronounced as to make it appear that an organism lacks the enzyme, although extracts of the organism con-

chrome *c* reductases (29, 30) and isocitric dehydrogenase (30) in the various fractions and find large amounts of the reductases in the microsomes while a high proportion of the dehydrogenase is in the soluble fraction. They were of the opinion that the rate of oxygen uptake by the mitochondria was mainly a measure of cytochrome reductase activity. However, on the basis of the following studies, we believe that in the mitochondria alone the rate-limiting reaction is phosphate breakdown.

We carried out phosphate balance studies on kidney mitochondria, whole homogenates and mitochondria plus nuclei (31). The mitochondria did not break down the added ATP until the

Fig 2 COMPARISON of slice activity with homogenate activity. Data from references 21-24

tain the enzyme in demonstrable form, as in the case of the pantothenicless mutants 5531 and 34556 of *Neurospora* (27). The more usual case will of course involve only modifications of enzyme activity.

The case of pyruvate oxidation in kidney may be discussed in somewhat greater detail, since studies with cell fractions are available for comparison (fig 3). The oxidation of pyruvate by rat kidney slices yields a Q_{O_2} of about 17, while that of the homogenate under optimum conditions is about 3-fold greater, or 52 (24, 25). When we examined the components of the kidney homogenates (28) we found that the nuclei and the S_2 supernatant were almost inactive, while the mitochondria possessed only 33 per cent of the activity of the homogenate. When the mitochondria were supplemented by either the nuclei or the supernatant fraction the activity was doubled.

In interpreting the stimulating effects of the other fractions in the presence of the mitochondria, it is necessary to consider what individual enzymes these fractions contain. Hogeboom and Schneider have studied the distribution of cyto-

Fig 3 COMPARISON of pyruvate oxidation by kidney slices, homogenates and cell fractions

substrate was depleted, while the whole homogenate dephosphorylated the ATP much sooner. When nuclei were added to mitochondria, the oxidative rate was doubled and the phosphate breakdown was also accelerated. Since the nuclei do not appear to contain the oxidative enzymes (29, 30) to account for the doubling of the rate, it is suggested that the oxidative enzymes in the mitochondria are adequate but that their potentiality can only be demonstrated by eliminating the rate limiting factor, namely the availability of the phosphate acceptor.

The next experimental step is the substitution of a phosphate acceptor system for the nuclear fraction, as a supplement to the isolated mitochondria, and such studies have recently been reported by Lardy (32) (fig 4). Mitochondrial fractions obtained from rat liver were supplemented with purified hexokinase or with creatine phosphorylase and the respective phosphate acceptor systems. It was demonstrated that as much as 400 per cent stimulation of oxygen uptake could be obtained, under conditions that are comparable to what we employed in the studies

with mitochondria and nuclei (28, 31) Kielly and Kielly (33) and the Lipmann group (34) have also observed stimulation of oxygen uptake when mitochondria were supplemented with hexokinase and glucose. These studies leave little doubt that the mitochondria are not primarily limited with respect to oxidative enzymes and that their oxidative rate is in fact limited by the rate at which phosphate acceptors are made available. On the basis of these facts we suggest that similar considerations may apply to slices of certain normal tissues, in other words, that the oxidative rate of these normal tissue slices may also be limited by the rate at which phos-

like to devote the remainder of our time to a brief discussion of methods

METHODS

In a recent review Borsook (38) stated that the incorporation of amino acids into proteins does not necessarily depend upon the direct participation of the nucleus. While this statement may be true, it was based upon observations with mitochondria and microsomes that were almost certainly not free of nuclear material, owing to the fact that the cell fractions were obtained from material that had been subjected to the blades of a Waring blender for 1½ minutes. This device is not suitable for this type of study on the formed bodies that occur in cells because under the conditions employed it tends to disintegrate both nuclei and mitochondria with the result that fragments of each contaminate the subsequent fractions, as will be described. The criteria for identifying these cellular components are not arbitrary, and while we are constantly looking for better criteria, some progress has already been made, as Dr Hogeboom has shown today. It is our purpose to stress the use of at least *two* different types of analytical measurements for checking the homogeneity of cell fractions. We generally express the measurements on each cell fraction in terms of a percentage of the value for the total tissue sample. The two measurements are chosen to characterize the desired component and the chief contaminant, respectively.

Consider the isolation of nuclei. It is quite certain by now that all of the DNA of the cell is in the nucleus, and that the nuclei are sedimented at relatively low speeds in the centrifuge as the preceding speakers have emphasized. There are two points to be stressed in connection with recovery of DNA, which is the first objective in nuclear separations. When glass or lucite homogenizers are employed the recovery of DNA in the nuclear fraction is routinely near 100 per cent (1). However when the Waring blender is used, the nuclei are completely disintegrated within 30 seconds in a KCl medium, according to reports from D. E. Green's laboratory (39, 40). Direct analytical evidence for nuclear disintegration in these preparations was reported by Schneider and Potter (28) who found only 74 per cent of the tissue DNA in the sedimented fraction. That under these conditions nuclear fragments contaminate subsequent fractions is shown in a report by Keller (41) who reported the

Fig 4 STIMULATION of pyruvate oxidation by the presence of a phosphate acceptor system (31)

phosphate acceptors are made available (cf 35, 26). This view implies that under appropriate conditions the oxidative rate of these normal tissue slices could be accelerated, and such increased rates of oxidation in tissue slices have of course been repeatedly observed in the presence of dinitrophenol and various other agents (cf 36, 37).

The experiments with isolated mitochondria, studied separately and in combination with other cell fractions or with a phosphate transferring system, provide models of the regulation of enzyme function in response to need, at the intracellular level. While a beginning has been made in this field, we feel that more rigorously defined preparations of cell fractions are needed for all studies of this type and therefore we would

isolation of 'microsome' fractions containing large quantities of DNA following the use of the blender. The second point is that the analytical recovery of 100 per cent of the DNA in the nuclear fraction is obtained with the use of trichloroacetic acid as in the original Schneider technique (42). Dr Recknagel recently found that when perchloric acid was used for the extraction (cf. 43) the cytoplasmic fraction gave a false test for DNA, which was easily recognized by taking the complete absorption spectrum.

The second objective in the evaluation of the nuclear fraction is to determine the extent of contamination by whole cells and by cytoplasmic fractions. This information is provided by the second measurement, which under ideal conditions would be an analysis for something completely absent from nuclei but abundant in cyto-

plasm or in sucrose of any molarity between 0.1 and 0.8 M occupy a large volume that is 5 or 6 times as great as the volume in isotonic KCl or in isotonic sucrose containing a small amount of electrolyte (0.01 M phosphate). In addition to the effect on the nuclear volume, the presence of the electrolyte increased the contamination by mitochondria as evidenced by the high succinoxidase content, which was 23 per cent of the total, and by the increased uptake of the mitochondrial stain, Janus Green B, as shown in the photograph.

We next turned our attention to a re-examination of procedures for the isolation of mitochondria, again using two types of measurements as a guide to homogeneity. For the present it has been assumed that succinoxidase activity can be used to characterize the mitochondria, while

Fig 5 EFFECT OF CENTRIFUGATION MEDIUM ON volume of the nuclear fraction. Each tube contains the nuclei from 1 gm. of rat liver. Suspension media were as follows: *Tube 1*, H₂O, *tube 2*, isotonic KCl, *tube 3*, isotonic sucrose, *tube 4*, isotonic sucrose plus 0.1M potassium phosphate buffer, pH 7.6, *tube 5*, isotonic sucrose plus 50 γ Janus Green B, *tube 6*, isotonic sucrose plus 0.1M potassium phosphate buffer, pH 7.6, plus 50 γ Janus Green B. Centrifugation at 400 $\times g$ for 10 minutes.

plasm. Here we have chosen the determination of succinoxidase activity. It cannot be claimed on the basis of available evidence that the succinoxidase system is completely absent from nuclei, but it is the best test that we have seen for the quantitative detection of cytoplasmic contamination of nuclear fractions. By the use of pestle homogenizers, isotonic sucrose containing no electrolyte, and a low gravitational force of 400 g , we have obtained liver nuclei containing only 4 per cent of the total succinoxidase in the homogenate. For lower levels of contamination, only a careful examination with the microscope can assure complete absence of mitochondria.

The effect of the centrifugation medium is demonstrated in the next slide (fig. 5) which shows the packed nuclei from one gram portions of cells from perfused rat livers. Nuclei in water

Fig 6 DIFFERENTIAL STAINING of mitochondrial and poorly sedimented layers. Centrifugation at 8000 $\times g$ for 10 minutes following removal of nuclei. *Tube 1*, unwashed particulate matter, *tube 2*, washed once, *tube 3*, 30 γ Janus Green B added, *tube 4*, 100 γ Janus Green B, then incubated at 38° C for 5 minutes. *Tube 5* shows incubated microsomes following addition of Janus Green B. The dark portion of the precipitate shown in *tube 4* was red.

PNA is being used to characterize the principal contaminant (microsomes). It is not implied that mitochondria contain no PNA, but it appears that they contain much less than the microsomes. Studies in the literature report rat liver mitochondria with PNA contents ranging from 5 to 40 per cent of the cellular PNA in normal rats on similar diets. The reason for this tremendous variation lies in the fact that the 'poorly sedimented' layer described by Schneider (1) has been removed by some investigators and left with the residue by others. It may be of interest to show a picture of this layer, and to show how a new application of the Janus Green stain has been employed by Dr Recknagel to differentiate the two layers. This stain is considered to be specific for mitochondria (44) and it has also

been known that the mitochondria reduce the dye to diethylsafranin, which is red (44). It was found that the differential staining could best be developed by including the dye in the medium prior to centrifugation and by incubating the packed particles at 38° for 5 minutes. In the presence of an excess of the dye, both the mitochondria and the poorly sedimented layer originally stain blue, but upon incubation only the mitochondria turn red so that a sharp line can be seen between the two layers (fig 6). The staining reaction and the reduction are optimum in isotonic sucrose, almost obliterated in 0.6 to 0.8 M sucrose, and weakened in hypotonic sucrose. In anaerobic suspension the reduction was stimulated by TPN but not by DPN.

Fig 7 DISTRIBUTION of liver PNA and succinoxidase activity at different centrifugal forces. The medium was 0.25M sucrose containing 0.01M phosphate pH 7.6. The poorly sedimented layer was not removed from the mitochondrial layer.

The next slide (fig 7) shows succinoxidase and PNA measurements on the residues obtained at different centrifugal speeds, with the poorly sedimented layer left with the residue. It is clear that the succinoxidase recovery reached a maximum at relatively low speeds, while the PNA content and the amount of the poorly sedimented layer (observed visually) continued to rise as the gravitational force was increased.

On the basis of these findings, we concur in the opinion of Schneider and Hogeboom (1) that the particles in the poorly sedimented layer, at least in the case of liver, are probably not mitochondria, and that they are probably microsomes. Further studies on the microsomes and on other tissues using these and other criteria of homogeneity are needed.

The data in figure 7 may be compared with data employing the Waring blender in which it was reported (40) that after 30 seconds in the blender 45 per cent of the succinoxidase was in the 'microsome' fraction, and by 60 seconds the proportion occurring in the 'microsomes' had increased to as much as 73 per cent. Less than 30 seconds was insufficient time to break up the tissue. We interpret these data to mean that the blender is unsuitable for cytochemical studies involving the methods of differential centrifugation as a prelude to studies on enzyme systems since it comminutes both the nuclei and the mitochondria to the point where they occur in the microsome and supernatant fractions. Further evidence regarding the increased phosphatase activity (45) and decreased oxidative capacity (46) of the blenderized preparations has been reported in other laboratories. We object to the use of the word 'homogenate' for these blender preparations because it is clear that their properties differ considerably from the preparations to which we originally applied the word. The possible usefulness of the word homogenate has been destroyed by its indiscriminate use so that it can no longer be used without qualification. However, it was never an appropriate term for what is actually a heterogeneous suspension of cellular components, and its misuse is not too serious. The misuse of the words nuclei, mitochondria and microsomes is much more regrettable, although all of us are probably guilty in varying degrees. Moreover, the avoidance of the terms is undesirable if the data are to be useful in a cytochemical sense. The homogenate that we have used was merely a stage in the evolution of techniques for the study of enzymes at the intermediate level between the whole cell and the soluble protein (6). At this level, we feel that an effort should be made to relate enzymology to intracellular physiology, by maintaining the formed bodies of the cell in intact form insofar as may be possible, and by working with the separate components of the homogenate alone and in defined combinations.

The experiments we have described have been carried out with isotonic sucrose and with liver and kidney. We are advised that this medium may be unsuitable for tissues such as thymus and it should be emphasized that the methodology in this field is far from established.

SUMMARY

This discussion may best be concluded with a plea for more rigorously defined cell fractions and more careful definition of speeds, media, and homogenates. We predict that further attempts to isolate cell components with a minimum of

post-mortem changes and to duplicate the intracellular environment will add greatly to our knowledge of intracellular control mechanisms. We believe that the understanding of these control mechanisms is our most important goal, because with such understanding comes increased power to cope with the problems of disease.

STRUCTURE AND FUNCTION OF NUCLEIC ACIDS AS CELL CONSTITUENTS

ERWIN CHARGAFF

*From the Department of Biochemistry, College of Physicians and Surgeons, Columbia University,
New York City*

IT is safe to say that living systems require the presence of both types of nucleic acid, or, in the case of parasitic systems, the presence of at least one. If, to use a designation of Schrodinger (1), one refers to the chromosomes as "the hereditary code-script," the great biological importance of all components of these nuclear structures, viz nucleic acids, proteins, and, perhaps, lipids, is obvious, unless one assumes that one or the other of these components has been added by Nature as a meaningless and purely decorative flourish. This is, however, not likely.

In animals and higher plants the desoxyribose nucleic acids (DNA) are exclusively or almost exclusively situated in the nucleus. Pentose nucleic acids (PNA) are present in the nucleoli and the various cytoplasmic elements, e.g. the mitochondria, submicroscopic particles, etc. Recent work with Elson (2) on the nucleotide composition of PNA in different fractions of rat liver cells has provided preliminary evidence of differences in composition between nuclear and cytoplasmic PNA. It is not yet known whether this will be generally true, but results, recently reported with Magasanik (3), seem to point to the presence in pig liver PNA of two differently composed fractions.

Whether DNA really is limited to the nucleus is not entirely certain, since the available cytochemical or cytophysical methods presumably require the presence of a compact mass of DNA and may not reveal its occurrence in a diffusely distributed form, as could be the case in the cytoplasm of egg cells (cf. 4). The bacterial cell represents a special case. Whether the microbial nucleus is the sole repository of DNA in microorganisms, cannot yet be decided with certainty.

BIOLOGICAL SIGNIFICANCE OF NUCLEIC ACIDS

The discussion of the biological significance of a ubiquitous cell constituent is, strictly speaking, superfluous. But there exist a few important instances pointing to a direct involvement of

nucleic acids, and some of them will be listed here briefly.

All virus preparations so far described are, or contain, nucleoproteins (cf. the recent survey of Davidson, 5). The same seems to be true of intracellular parasites, such as rickettsiae (6, 7) or paramycin (8).

Specific DNA preparations are known which are able to induce the transformation of bacterial types. This extremely important phenomenon, first discovered in pneumococci (9), has later been shown to operate also in *B. coli* (10) and in *Hemophilus influenzae* (11, cf. also 12). The possibility that reactions of this kind are of more general biological importance and not limited to the field of bacterial transformations cannot be rejected. What appears particularly remarkable is that it is here the free nucleic acid and not a nucleoprotein (as in the case of viruses) that is able to impose its own synthesis on the receptor cell, whereas in general nucleic acids seem to occur in cells only in the form of conjugated nucleoproteins. The mechanisms through which these transformations take place and the chemical features distinguishing these biologically active DNA specimens are completely obscure. There is, however, little doubt that it is the bacterial DNA itself, or a particular DNA fraction present in the transforming preparations, which is the carrier of activity. Recent work on the agent operative in the transformation of *H. influenzae* has shown that highly purified DNA preparations from two types are active in extremely low concentrations: 0.0004 γ of DNA per cc. in type b, 0.01 γ in type c (13).

The investigation of the relative efficiencies of different wave lengths of ultraviolet light has yielded curves closely resembling, but not entirely identical with, the UV absorption spectrum of nucleic acids. This work, mainly due to Stadler and Uber, Hollaender and Emmons, and Knapp and Schreiber, has been reviewed by Lea (14).

A certain degree of constancy, within the same species, of the DNA concentration per

diploid nucleus, and of roughly one-half this amount per haploid sperm nucleus, has been discovered by Boyin and his collaborators (15, 16, 4) and confirmed in other laboratories (17, 18)

DNA is in its composition identical in different tissues of the same species (19). Moreover, in the few cases where comparison was possible, no chemical differences have been observed between the composition of the DNA from the sperm cells and from differentiated tissues of the same species, in contrast to the very different composition of nuclear proteins in such instances.

DESOXYRIBONUCLEIC ACIDS

All DNA preparations that have been studied in detail have several features in common. They are asymmetric molecules of high molecular weight (around 10^6), yielding extremely viscous solutions. They appear to contain the same desoxy sugar, namely 2-desoxyribose. They contain two purines, adenine and guanine, and two or three pyrimidines, viz thymine and cytosine, and in several cases (20) also 5-methylcytosine. The desoxyribonucleotides released enzymatically from calf thymus DNA appear to be the 5-phosphates (21, 22).¹

The conclusions to which our work has led us have been summarized recently (19, 24) and I shall limit myself here only to the main points.

1 DNA is in its composition characteristic of the species from which it is derived. This can in many, but not in all, cases be demonstrated by determining the ratios in which the individual purines and pyrimidines occur. There will, how-

ever, be very many borderline cases in which such differences in composition are not sufficiently significant to permit their use as the sole criterion of differentiation. The most important question of the sequence in which, in a particular nucleic acid, the nucleotides follow each other has so far barely been approached. The elaboration of methods for sequence analysis is, perhaps, one of the most urgent problems in nucleic acid chemistry, since differences in nucleotide sequence may very well be among the determinants of chemical and biological specificity.

2 No differences in composition have so far been found in DNA from different tissues of the same species. This provisional conclusion refers only to the over-all composition. It is in this connection noteworthy that no chemical differences appear to exist between the composition of DNA from normal human tissue (25) and that of preparations from human cancer tissue (26).

3 The tetranucleotide hypothesis is incorrect.

4 There exist a number of regularities. Whether these are merely accidental cannot yet be decided. In almost all DNA preparations studied until now the ratio of total purines to total pyrimidines never was far from 1. Similarly the ratios of adenine to thymine and of guanine to cytosine were near 1.

5 There appear to exist two main groups of DNA, namely the 'AT type,' in which adenine and thymine predominate, and the 'GC type,' in which guanine and cytosine are the major constituents. The latter has so far been found only in certain microorganisms (27).

Data to support these conclusions have, in the main, been presented in previous publications and were summarized recently (19, 24). I should like to limit myself here to the discussion of a few as yet unpublished results. The study of the composition of the DNA of salmon sperm (28) has brought out some of the regularities mentioned before particularly clearly (tables 1 and 2). This substance belongs to the 'AT type'.

Another investigation, undertaken in collaboration with G. Braverman, deals with the DNA of wheat germ and the course of its degradation by crystalline pancreatic desoxyribonuclease. Previous work in our laboratory on the enzymatic disintegration of calf thymus DNA (29) had shown it to proceed according to a peculiar and complex pattern. The action of the enzyme resulted in the formation of dialyzable fragments and of a dialysis residue (core). The latter was

¹ In this connection mention may be made of experiments with D. Elson on the separation of the desoxyribonucleotides by filter paper chromatography. With neutral aqueous solutions of the nucleotides and the techniques described for the ribonucleotides (23) quantitative separation in the form of compact spots was obtained. With the buffered isobutyric acid-ammonium isobutyrate system (pH 3.6) the nucleotides were, in the order of increasing distance from the starting point, aligned as follows (with the distance of the adenine nucleotide arbitrarily taken as 100 and the relative distances of the other nucleotides placed in parentheses): 1) Desoxyguanylic acid (53), 2) thymidylic acid (66), 3) desoxycytidylic acid (80), 4) desoxyadenylic acid (100), 5) desoxy-5-methylcytidylic acid (137). We are indebted to Dr. W. E. Cohn for the nucleotides.

characterized by greatly increased ratios of adenine to guanine, thymine to cytosine, purines to pyrimidines, and by greater resistance to enzymatic attack. Preliminary results of studies of this type on wheat germ DNA are presented in table 3. The analytical findings on the intact DNA are in good agreement with analyses recently reported for the same nucleic acid from

two other laboratories (30, 31). The figures given here for the '19% core' and the '8% core' refer to the dialysis residues recovered when 81 and 92 per cent of the DNA respectively had been converted by the enzyme to dialyzable fragments. The trend of degradation appears similar to that observed with calf thymus DNA.

The molar ratios found in the DNA specimens studied in our laboratory are compared in table 4. The tendency toward certain regularities will be observed. The figures for hen DNA (chicken erythrocytes) and for the DNA from the K-12 strain of *B. coli* must be considered as preliminary. Both components were studied in collaboration with B. Gandelman. The DNA of *Hemophi-*

lus influenzae, type c, was studied by S. Zamenhof. A few points are noteworthy. In the case of wheat germ DNA, methylcytosine and cytosine apparently must be considered together, if the regular ratios, observed in most other instances, are to be obtained. Another remarkable fact is that the regularities are maintained even in the nucleic acids of the 'GC type' despite the complete inversion in individual ratios.

As was already mentioned before, it is almost impossible to decide at present whether these regularities are entirely fortuitous or whether they reflect the existence in all DNA preparations of certain common structural principles, irrespective of far-reaching differences in their indi-

TABLE 3 WHEAT GERM DNA, INTACT PREPARATION
AND ENZYMATICALLY PRODUCED CORES (IN MOLES
OF NITROGENOUS CONSTITUENT PER MOLE OF P
IN HYDROLYSATE)

CONSTITUENT	INTACT DNA	19% CORE	8% CORE
Adenine	0.27	0.33	0.35
Guanine	0.22	0.20	0.20

Total pyrimidines	0.49	0.42	0.37
Recovery	0.98	0.95	0.92

vidual composition and the absence of an easily recognizable periodicity. It may be assumed that the nucleic acids as we know them today, as for that matter also the proteins, are the result of an age-long selection process in the course of which many less suitable or less stable components must have been eliminated. One could speak of the survival of the fittest nucleic acids. Such macromolecules will exhibit diversity and uniformity at the same time, since they are called upon to perform, in diverse species, the same tasks. It is, therefore, perhaps not astonishing that the nucleic acids will share certain features that may be directly connected with their stability or their ability to form conjugated nucleoproteins. One property which is quite striking is the uniform absorption spectrum in the ultraviolet of all highly polymerized DNA specimens, both with respect to the position and the intensity of the

absorption maximum. The center of absorption fluctuates only between 257 and 261 m μ and the (ϵ)P is around 6600. Another surprising feature is the balance between amino groups and enolic hydroxyls in all DNA preparations examined by us (See last column of table 1.) Even in the core preparations, this ratio changed only very little.

But let us return for a moment to the other outstanding characteristic of nucleic acids, viz. their diversity. If we accept the evidence of the existence of species specific DNA, then there arise many new questions, both of a biological and chemical nature. DNA presumably is an important part of the chromosomes and may be

periodicity in a nucleic acid chain. Any simplified assumption with respect to periodicity has been disproved by the studies on the course of action of deoxyribonuclease on the DNA of calf thymus (29) and of wheat germ. The composition of both the dialyzable degradation products and the dialysis residues, the 'cores,' exhibited continuous and characteristic changes with respect to the distribution of purines and pyrimidines. One must conclude that the sequence is highly aperiodic and that it is not inconceivable that the same cellular DNA could give rise to many different nucleoproteins, depending upon the shape and configuration of the particular protein

TABLE 4. MOLAR RATIOS IN DNA PREPARATIONS OF DIFFERENT ORIGIN

SOURCE	ADENINE TO GUANINE	THYMINE TO CYTOSINE	ADENINE TO THYMINE	GUANINE TO CYTOSINE	PURINES TO PYRI- MIDINES	AMINO GROUPS TO ENOLIC HYDROXYLS

¹ In these computations the sum of cytosine and methylcytosine was used. If cytosine alone is considered, the thymine to cytosine ratio is 1.62 and that of guanine to cytosine 1.33.

surmised to be involved in their biological functions. Does this mean that a cell contains as many different DNA individuals as it contains genes? Or can one and the same species-specific DNA form so many three-dimensional structures, in connection with the proteins to which it is attached, that the genic requirements are fulfilled? (For a more detailed discussion of some of these points, cf. 32.) This question, as so many others in this field, cannot yet be answered. No way has as yet been found to fractionate a family of very similar macromolecules which may differ in no more than the sequence of a few of their component nucleotides. But one could perhaps say that the more regular the arrangement of nucleotides is in a given DNA, the less the chance of its forming many different specific structures. And this brings us again to the very important question of nucleotide sequence and

It must, moreover, be understood that the recognition of periodicity, i.e. the presence of recurring units, will be particularly difficult in a macromolecule of the type of DNA. If, for instance, in a chain composed of 3000 nucleotides a particular sequence of 100 consecutive nucleotides were repeated 30 times, this periodicity could not be recognized, unless we had a method producing cleavage only at the points where these repeating units are joined. In other words, the perception of periodicity would require the proper distance for a bird's-eye view which will not be easy to attain.

Another approach to the problem of sequence analysis in DNA may be seen in the study of its controlled chemical degradation. That the purines can be detached from a nucleic acid with much greater ease than can the pyrimidines, has long been known, but the resulting end product,

thymic acid, was rather nondescript. In collaboration with M. E. Hodes and C. Tamm it has been possible to develop procedures, soon to be published, in which all purines could be cleaved from a DNA preparation, leaving behind a nondialyzable product in a yield of about 94 per cent that retained all the pyrimidines of the original DNA in unchanged proportions. We have designated preparations of this type as apurinic acid. These compounds may prove of interest for structural studies on DNA, since the position in the DNA chain of the initially present purine nucleotides is now marked by reactive aldehyde groups. The properties of a typical preparation of apurinic

acid are contrasted in table 5 with those of the calf thymus DNA specimen that served as the starting material.

PENTOSE NUCLEIC ACIDS

Time does not permit an adequate discussion of the chemistry of PNA. In the past few years, significant contributions to this field were made by Gulland, Kerr, Schmidt, Allen, Loring, Cohn, and many other workers. I should like to make brief mention of some recent work done by B. Magasanik in our laboratory (3) in which the course of action of crystalline ribonuclease on PNA from yeast and from pig liver was studied with the use of chromatographic and spectroscopic procedures. About 60 to 70 per cent, or in some cases somewhat more, of the nucleotides present in the initial substrates were liberated by enzymatic action as rapidly dialyzable nucleo-

tides of low molecular weight. This fraction consisted of free cytidylic and uridylic acids, which comprised a high proportion of the total pyrimidine nucleotides, and of combined purine and pyrimidine nucleotides. All PNA preparations yielded a nondialyzable residue, resistant to enzymatic attack, which was found to consist to about two thirds of guanylic acid and of varying amounts of the other nucleotides. A selection of these experiments is presented in table 6. These and other findings have led us to

TABLE 6 ACTION OF RIBONUCLEASE ON PNA

SOURCE	FRACTION	NUCLEOTIDE COMPOSITION (AS MOLES/100 M NUCLEOTIDE IN STARTING MATERIAL)				
		Guanylic acid	Adenylic acid	Cytidylic acid	Uridylic acid	Total
Yeast	Starting	30	21	23	26	100
	Dialyzable (total nucleotides)	18	15	19	26	78
	Dialyzable (mononucleotides)	0	0	14	19	33
	Core	66	18	8	8	
Pig liver	Starting	36	19	29	16	100
	Dialyzable (total nucleotides)	18	14	26	15	73
	Dialyzable (mononucleotides)	0	0	18	10	28
	Core	71	15	0	14	

certain conceptions concerning the specificity of ribonuclease and the structure of PNA, but reference must be made to a detailed article which is in press (3).

FINAL REMARKS

It is fitting to conclude this all too sketchy survey with a confession of ignorance. What our studies have taught us more than anything else is how little we know as yet about the chemistry of nucleic acids. The chemical specificity of macromolecules and the interactions between them through which the organization of the cell is maintained can only partly be understood in

terms of our present knowledge. In the approach to a scientific problem two principles are operative: generalization and simplification. Both are necessary and both dangerous. It is obvious that we can learn more geometry from the illustrations in a textbook on projective geometry than from the beautiful pictures in Sir D'Arcy Thompson's *On Growth and Form*. But it is difficult to say where the danger line lies beyond which over-simplification will produce a dogmatic ignorance.

Should we stress the multifariousness of Nature, which makes us forget the simplicity of its basic designs, or should the essential shape win over the accidental form? In Wycheley's *The Country Wife* a quack is addressed as follows: "Doctor, thou wilt never make a good chemist, thou art so incredulous and impatient." If patience and credulity were all the chemist needed, the problem of the nucleic acids—still so baffling and elusive—would have been solved a long time ago.

INFLUENCE OF NON-PROTEIN CALORIES ON PROTEIN METABOLISM¹

PEARL P SWANSON

*From the Home Economics Research Department, Iowa Agricultural Experiment Station, Iowa
State College, Ames, Iowa*

THE PRESENCE of energy-producing foods in the diets of all peoples reflects a primary metabolic demand. Sources of energy must be provided for the work of the body—intrinsic and extrinsic—for the maintenance of body heat, and for the regulation of the myriad biochemical reactions governing the physiological economy. There is, however, an accumulating body of evidence indicating that both carbohydrate and fat play a role over and beyond the provision of calories. That the total energy balance and the nitrogen balance are inextricably interwoven is evident. However, a review of the information found between the covers of that repository of fact and interpretation, *The Biology of Human Starvation* (1), indicates that, in respect to the three basic nutrients, carbohydrate, fat and protein, the requirements of man as we meet him in his ordinary walks of life have not been defined clearly in terms of practical working recommendations that will take into account the many and varied situations in which he finds himself. As in the past, knowledge of the nutritional requirements of human beings will grow as facts accumulated in research laboratories of this and other countries are interpreted and applied. I have chosen, therefore, today to confine myself largely to the presentation of experimental studies that may have significance in solving the many problems that are met in the feeding of the human race, the world over, in times of peace and war.

The story of the dietary interrelation of proteins, carbohydrates, and fats in the maintenance

of nutrition had its beginnings in the laboratories of the great masters of physiology in Europe. As we, with our large fund of new nutrition knowledge and with research facilities of the highest order, look back to their achievements, our wonder ever grows that they could have accomplished so much. And certainly it is a challenge to the modern nutritionist to pick up the threads where these great men left off and to weave them into a finished tapestry.

Nitrogen balance is a tool that has been used by many workers in estimating the part played by non-protein calories in the establishment of nutritional state. I think we can say, in the main, that experimental studies show that nitrogen retention is a function in part of the caloric intake. However, there are many factors whose influence is not yet fully understood or appreciated that affect the metabolic interplay of these nutrients. What some of these factors are and how they work will be the theme of this discussion.

CALORIC RESTRICTION

It would seem that an understanding of caloric influence on the *endogenous* nitrogen metabolism characteristic of protein starvation should provide a base for fundamental first approximations. In figure 1A is shown the effect of systematic reduction of calories on the catabolism of 4 groups of rats as measured by the quantity of nitrogen excreted in the urine (2). The animals in each group had been protein-depleted under a standardized set of conditions and were catabolizing body tissue at a constant rate. The basal diet they received was protein-free, but otherwise adequate. When consumed *ad libitum*,

¹ Journal Paper, No. J-1958, Iowa Agricultural Experiment Station, Project 995

it provided approximately 19 Cal/rat/day. In this experiment, the ration was fed in quantities that supplied 100, 75, 50, or 25 per cent of the calories normally consumed by the rat. The data indicate that the first two reductions in caloric intake although inducing some increments in urinary nitrogen do not impose stresses to which the animals cannot make physiologic adaptation. It is only when the energy intake is reduced to one-fourth of the normal requirement that the deficit becomes critical and the animals no longer are able to maintain the integrity of their tissues. The increment in the output of urinary nitrogen is immediate and marked just as soon as the caloric deficit is imposed.

Fig 1 URINARY EXCRETION of nitrogen by rats fed rations of different caloric values

The way a protein-starved animal uses tissue protein under conditions of caloric restriction is reflected in its handling of protein derived from *exogenous* sources (fig 1B). To the diets of the animals in this group, egg white protein was added in a quantity that supported nitrogen equilibrium when the ration was of *adequate energy value*. It may be seen that there is a trend toward an increased excretion of nitrogen in the urine as the energy value of the diet drops to one-half of the normal intake. On the whole, the average rates of metabolism of the rats in each group are not very different than they were when the diet contained no nitrogen. But further reduction in caloric intake leaves a marked imprint, and the animal throws all of the nitrogen of its food protein away so that it may use the non-nitrogenous portion as well as similar moieties arising from the degradation of body tissue in satisfying its demand for energy. The increment in urinary nitrogen when the diet supplies

only one-fourth of the needed calories is approximately equal to the quantity of nitrogen ingested.

PHYSIOLOGICAL STATUS

The experiments just described are based on the response of rats undernourished in respect to protein. Of as great interest is the influence of the non-protein calories of the diet on the manner in which animals better nourished in this respect utilize protein provided in their food, a subject studied in detail by Dr. Allison's group at Rutgers University (3). Again, when dietary protein is administered—this time to the dog—in a quantity that supports nitrogen equilibrium at full caloric intake, there is a continuously augmented excretion of nitrogen in the urine as the energy value of the diet drops from a high to a low value. Relative increments are of a somewhat greater order than they are in standardized protein-starved rats. However, as early as 1946, Allison and his co-workers showed that despite these constantly increasing urinary losses the nitrogen balance index of the dietary protein fed is not altered until the energy provided by the ration is less than one-half the normal requirement of the animal (4).

When the diet supplies more than 50 per cent of the needed calories, the internal reserve that an animal in a reasonably good state of nutrition possesses in its hepatic and plasma proteins acts like a safety valve. These proteins when drawn upon in times of emergency may provide sufficient energy to satisfy caloric needs and thereby permit utilization of food nitrogen. If the period of stress is not too prolonged, the animal apparently suffers no injury over and beyond the diminution of tissue reserves for meeting future dietary crises.

The picture in general supports the views of Bosshardt and his co-workers (5) that an animal responds in two ways to a systematic reduction of the caloric value of the diet. A nominal limitation causes the animal to draw on existing reserves to get the energy its food is not supplying, then more drastic deprivation forces it to use both food and body nitrogen for energy purposes, and a marked breakdown of body tissue occurs.

BODY STORES

The significance and importance of these body stores of nitrogen have been stressed by the Rutgers group (3). In animals possessing such

tissue reserves, metabolism under conditions of reduced caloric intake does not remain static, but rather drifts into the state where nitrogen retention is markedly reduced. The speed at which the drift occurs and the character of the metabolic response depend on the size of the internal stores of protein. A dog, for example, with well-filled tissue reservoirs passes first into acute negative balance when a severe caloric restriction is imposed. Then it drifts toward nitrogen equilibrium, but before this state can be achieved, the impact of the caloric deficiency forces the animal into acute negative balance. On the other hand, with the first restriction of calories, an animal whose initial reserves are low in protein slips immediately into positive balance, but then suddenly and rather dramatically drops into negative balance—perhaps a full 25 days earlier than does the better nourished dog. These experiments point to the fact that situations exist where an animal may be in nitrogen balance but still losing body tissue. The function of tissue reserves in padding metabolic processes against the shock of dietary imbalance may explain in part why Keys and his co-workers (1) did not observe a trend toward a correlation of nitrogen retention and caloric intake until the men had lived on the semi-starvation diet for more than 12 weeks.

RESISTANCE TO CALORIC RESISTANCE

It is interesting also to note that Allison (3) sometimes encounters a marked resistance to the nitrogen-depleting effect of a restricted caloric intake in individual dogs. Some of these animals are able to utilize dietary protein at full efficiency for as long a time as 150 days. Exploration of the reason will yield information, I am sure, that will enlarge our comprehension of the general problem.

QUANTITY OF PROTEIN IN THE DIET

The quantity of protein in the diet also bears a major relation to the response that an experimental animal may make to caloric additions or restrictions. Increasingly higher planes of nitrogenous utilization are established in mice consuming constant quantities of protein by additive quantities of calories. These, however, are enhanced further by increments in the dietary protein. It has been found in human experiments (6, 7) that, while 1500 Calories will support retention on a low protein intake—approximately

the critical level—900 Calories are ample when the protein intake is doubled. On the other hand, we see in the 'Minnesota experiment' that in rehabilitation additions of protein to rations ranging in energy value from 2000 to 3000 Calories per day exert no favorable influence on the retention of nitrogen (1). It indeed will be of both theoretical and practical interest to learn the lowest combination of protein and non-protein calories that will sustain nitrogen equilibrium under a variety of conditions.

CALORIES AND THE 'TIME FACTOR'

The effect of the elapse of time that may occur between the feeding of the protein and carbohydrate moieties of the diet on the utilization of nitrogen has intrigued several groups of investigators for some time. There is Geiger's recent contribution (8), that in protein-depleted as well as in infantile rats (9), separate feeding of the carbohydrate and protein portions of the diet results in a diminished retention of nitrogen. In explanation, Geiger suggests that the simultaneous presence of carbohydrate and protein in the diet induces a continuous flow of the prerequisite essential and non-essential amino acids at a rate that is commensurate with the metabolic demands of repleting or growing tissue (10). Undoubtedly, Dr. Geiger will discuss the interesting phenomenon today. Indeed, his concept of the gastro-intestinal dynamics involved (11) may be a basis for explaining the extraordinary demand for calories in the attainment of nitrogen balance by young men ingesting pure amino acids and ammonium salts as their sole source of dietary protein (12).

In support of Geiger's views is Leverton's observation (13) of the protective influence of additional calories in alleviating the negative nitrogen balance induced in young women subjects by the exclusion of animal protein from one meal (14). This response occurs when the daily intake of protein is approximately 43 gm/person/day. Of interest is the fact that failure to include animal protein in each of the day's three meals is not associated with negative nitrogen balance when the daily intake of protein is raised to 63 gm, and that, with the inclusion of this much protein in the diet, the caloric intake may be as low as 1400 Cal/day with no adverse effects (15). So, quantity of dietary protein, the non-protein calories of the diet, the time factor, and the relative distribution of high quality protein in the

day's meal are intertwined together in the complex picture of protein utilization

DIETARY SOURCES OF NON-PROTEIN CALORIES

Fat is regarded often as being wholly interchangeable with carbohydrate on a metabolizable energy basis. Also, it is generally assumed that the protein sparing effect of carbohydrate is considerably greater than that of fat when subjects ingest the same quantity of protein. Furthermore, in complete protein starvation, it is believed that it is carbohydrate, and not fat, that has the property of sparing body protein (16). Under conditions of caloric restriction, however, we have found in our laboratory that fat exerts a profound body-sparing effect when included in protein-free diets fed to rats. Indeed,

The nitrogen retention of all animals in an experimental series, when consuming a ration poor in nitrogen but of full caloric value, is determined in a balance test beginning with the 19th day and lasting either 5 or 7 days. Then part of the animals are fed nitrogen-poor diets of reduced caloric value. Four days are allowed for dietary adjustments, after which nitrogen balance is determined again over an interval comparable in length of that of *period 1*. The remaining animals in the experimental series are continued on the full caloric diet and their balances redetermined.

Thus, the performance of the rats in any experimental group is controlled in two ways: i.e. by their own behavior in *period 1*, and by the performance of another set of animals cata-

FIG 2 EXCRETION OF NITROGEN during successive intervals by rats fed a nitrogen-low diet.

the data suggest that fat has unique properties in regulating the course of the protein and perhaps the energy metabolism (17).

In these experiments, as in those previously described from this laboratory, the catabolism characteristic of protein-starved rats on a full caloric diet serves as the reference point in studying the influence of dietary modifications—in this case, the inclusion or omission of dietary fat in daily food quotas of descending caloric value. Male rats, 6 months old, are brought to an approximately steady state of nitrogen metabolism as judged by the quantity of the element excreted in the urine (fig 2). This condition with our particular stock animals prevails following maintenance for 18 days on a protein-free but otherwise adequate diet, and continues for another 14 to 16 days. All metabolic observations are made within this last interval of time. Two series of animals are prepared thus for study, the first group receiving a high fat ration during the period of depletion, the second a low fat diet

bolizing body tissue at the rate they would have been doing had no dietary modification been imposed.

The basal high fat diet used contains 10 per cent each of lard and butter fat, 38 per cent of the calories coming from fat (table 1). Fifty mg of vegetable oil supplement each diet. In the first experiments to be presented, the rations were offered *ad libitum* in *period 1*, and then held at this level of consumption in *period 2*. The rats so adjusted their intake of food that the average caloric value of the daily food quota of either the high fat or the low fat diet was approximately the same, i.e. 49 Calories. The vitamin mixture supplementing these basal diets contained all the recognized essentials.

In figure 3 are shown the nitrogen balances in *period 2* of rats fed the two basal diets—high fat and low fat—at four levels of caloric intake. The similarity in the rates of catabolism at normal and three-fourths normal caloric intakes suggests that the rats in the low fat group are not penalized

by the omission of the nutrient. Reducing the calories below this point, however, results in an intensification of the metabolic processes. Rats fed 12 Calories of the low fat diet, for example, lose tissue equivalent to 410 mg/nitrogen/100 gm body weight in 7 days, those given the high fat diet, 266. The findings have some counterpart in the observations of Pearson and Panzer (18), who report that the loss of the essential amino acids in the urine and stools of rats is considerably reduced when corn oil is a dietary component.

TABLE 1 COMPOSITION OF BASAL DIETS

DIETARY COMPONENTS	HIGH FAT DIET	LOW FAT DIET
	gm	gm
Dextrin	73	93
Lard	10	0
Butterfat	10	0
O & M salts	4	4
NaCl	1	1
Ruffex	2	2
Total	100	100
Cal/gm	4.8	3.8
Av intake in Cal/day	49	49
	(18 rats)	(36 rats)

In another series of experiments in which food intakes were controlled on the basis of *ad libitum* ingestion in period 1, the effect of varying the fat content in the diet was investigated (fig 4). The rations, isocaloric in value as fed, contained 20, 15, 10, 5 and 0 per cent of the butter fat-lard combination and were offered in quantities equivalent to 100, 75, 50, and 25 per cent of the normal energy requirement. The data depicted in the figure indicate that the nitrogenous metabolism of the animals is not altered until the dietary fat is reduced by 10 per cent, then the animals given the diet containing one-fourth the normal number of Calories go into a tailspin. The same condition prevails when the fat component is reduced further. In order to simplify comparisons, the nitrogen balances of all the groups whose caloric intake was held at one-fourth normal have been collected in figure 5. Seemingly, a ration should contain at least 15 per cent fat if it is to exert a protective action against the disintegration of body tissue induced by severe caloric restriction in a protein-starved rat.

We have obtained considerable evidence that

fats originating from different plant and animal sources vary in their capacity to protect against the body catabolism characteristic of the present experimental situation. Discussion of the relative merits of different fats does not seem warranted until results have been replicated and confirmed. Some related problems have been discussed recently by Barki, Collins, Elvehjem and Hart (19).

Fig 3 NITROGEN BALANCES induced by feeding protein-free diets high and low in fat and of graded caloric value

Inasmuch as rats fed rations deficient in protein involuntarily restrict their consumption of food, it seemed important to rule out the possible influence of inadequate food intake by more rigid control of this factor. Hoover, therefore, working in our laboratory, studied the response of animals to the force feeding of protein-free diets providing 100 per cent and 25 per cent of the daily energy requirement (20). The rations were made into slurries of the same caloric density, and the portions of each administered daily provided either 56 or 14 Calories/300-gm

rat (fig 6) Again, the presence or absence of fat in the diet is not reflected in any change in the total nitrogen balance when the animals are administered food supplying the full quota of necessary energy. Forced feeding, however, dramatically aggravates the rate of catabolism when only 14 Calories are given. Negative balance in these rats now is 1465 mg/300 gm rat/5 days, in contrast to 514 in the restricted group of fat-fed rats given the same number of calories in the form of the high fat diet.

madequate flood of nutrients from the gastrointestinal tract.

Nitrogen balance data presented thus far suggest that if the animal receives its full asset of calories, the removal of fat from the protein-free diet inflicts no handicap in the animal's adjustment to the absence of dietary protein. But before this conclusion is reached, let us examine other data. It was noted, for example, during the course of various force feeding experiments that a number of rats always died, and that this

FIG 4 NITROGEN BALANCES induced by feeding protein-free rations of varying fat content and of graded caloric value

A comparison of the data recorded in table 2 would indicate that when *ad libitum* feeding is employed, deprivation of calories in the form of both carbohydrate and fat increases the catabolism about 1.8 times, in the form of carbohydrate alone, 3 times. On the other hand, when force feeding is employed, the latter ratio becomes 5.

Why force feeding aggravates the unfavorable response to the ingestion of the low fat diet is a moot question. It should be noted that the controlled feeding regime reduces variation within a group. Perhaps these data indicate that the loss of appetite associated with the ingestion of inadequate diets represents a protective physiological mechanism against metabolic obstacles encountered in the handling of a qualitatively

mortality occurred in the group receiving the full intake of the low fat diet (table 3). In the first 3 experiments listed, mortality in the group ranged from 30 to 50 per cent, whereas none succumbed in the groups fed the high fat ration. The response of group IV shows the effect of offering the daily quota of food in three feedings rather than two, and of equalizing the densities of the food slurries by the addition of ruffex to the high fat diet. It must be of significance that of the 207 rats observed deaths occurred only among the groups fed the fat-poor diet. Also it is noteworthy that no rats in either group maintained on restricted caloric intake died.

I am wondering here if we may not have evidence of an acute fat deficiency disease precipitated by the strain of metabolic adjustment to

a protein-free diet Decker and his co-workers (21) have written recently that chronic essential fatty acid deficiency may culminate as an acute syndrome by the imposition of various stresses and strains

Fig 5 NITROGEN BALANCES when rats are fed protein-free diets of varying fat content and supplying only one fourth the needed calories

Fig 6 NITROGEN BALANCES induced by the force feeding of protein-free diets high and low in fat at two caloric levels

In studying further the effect of the removal of dietary fat, determinations of the partition of nitrogen in the urine (fig 7) disclosed an interesting alteration in the pathway of nitrogen metabolism when carbohydrate in restricted quantities served as the sole source of energy. It is not possible to present all data today, but it should

be indicated that a complete partition was made, and that in every experimental group the sum of the nitrogen present in the various components equalled the total excretion of nitrogen

Restricted caloric feeding induces a high excretion of urea in the fat-fed group. The increment is over two and one-half times greater, however, in the group receiving the low fat diet. But of greatest interest is the extremely large

TABLE 2 FIVE-DAY NITROGEN BALANCES WHEN CARBOHYDRATE CALORIES REPLACE FAT CALORIES IN THE DIET

excretion of ammonia nitrogen in the urines of this group of rats

Examination of these data, in connection with the concentrations of urea nitrogen and amino nitrogen in the blood, may be of interest (table 4). Feeding the low fat ration at full caloric intake results in an increment in the relative concentration of amino nitrogen in the blood over that in the blood of rats receiving adequate calories and fat in their ration. Some of this apparently spills over into the urine, and chromatographic determinations of amino acids therein disclose their presence in largest quantities in

the urines of rats fed unrestricted amounts of the low fat diet

The response of the rats in the low caloric-low fat group permits interesting speculation. What initiates the tremendous outpouring of nitrogen when this ration is fed in the first instance, and why does the animal receiving fat in its diet seemingly do a better job in adjusting to the stress of caloric restriction in protein starvation than its carbohydrate fed control? Perhaps the speeding up of the catabolic processes may reflect

suggests that the animal, in the absence of fat, is unable to take acidic intermediaries arising in the catabolic freeing of amino acids through the metabolic transformations required for their utilization as energy, and the kidney is forced to manufacture ammonia to care for the excretion of these intermediaries

There are other evidences of an impaired carbohydrate metabolism. Inability to convert the non-nitrogenous portions of the degraded protein molecule into glycogen is shown by an extremely low reserve of glycogen in the livers of the rats fed the restricted low fat diet, i.e. 0.7 per cent vs 2.0 per cent in the fat-fed groups. The glucose tolerance curves of the four groups

Fig 7 UREA NITROGEN and ammonia nitrogen in urines of rats fed protein-free diets high and low in fat

TABLE 4 CERTAIN NITROGENOUS CONSTITUENTS IN URINE AND BLOOD

14	Low fat	875	349	4	31	18

the increased specific dynamic effect of a simultaneously metabolizing pool of carbohydrate and protein in relation to one of fat and protein (22). But I do not believe that this is all of the answer.

Possibly, here, there is a block in the course of the carbohydrate metabolism. Normal rats on restricted caloric intakes and receiving the same quantity of nitrogen in their food protein as the rats in this experiment liberate from tissue sources can transform the nitrogen of their food amino acids into urea, thereby presumably deriving full energy value from the non-nitrogenous portion. The high proportion of ammonia nitrogen to urea nitrogen in the urine of a calorie-starved rat

Fig 8 GLUCOSE TOLERANCE curves of rats fed the stock ration and various modifications of a low nitrogen diet

in relation to that of normal stock animals are also interesting in this connection (fig 8). The tolerance of the rat receiving its full caloric quota of the high fat diet most nearly approaches the normal. Inanition may explain the lower tolerances of the rats fed restricted number of calories—either high fat or low fat—but it is significant that the average tolerance curve of the animals with a *luxus* consumption of carbohydrate calories falls in the same range as the tolerances of the rats restricted as to their caloric intakes. On the whole, the animals maintained on the low fat diets have many characteristics that are diabetic-like in nature. Others have noted that rats subsisting on a low fat diet cannot tolerate the increment in metabolic rate induced by the feeding of thyroid (23).

Very pertinent in this connection is the sug-

gestion from the work of Swift and his co-workers at the Pennsylvania State College, that rats fed diets containing fat use energy derived from dietary sources more efficiently than animals on a low fat dietary regime (22). In the words of these workers, the presence of fat in the diet confers "economy of utilization of food energy." Supporting this hypothesis that fat is needed for the maximal use of energy are the observations of several groups of workers showing that, under differing experimental conditions, inclusion of fat in the diet is associated with an increased capacity for work (24, 25).

Fig 9 NITROGEN BALANCES of rats fed protein-free diets high and low in fat when methionine is added as a dietary supplement

Possibly our own observations that methionine seems to play a role in these metabolic conversions will provide a clue in the final unraveling of the problem (fig 9).

Its addition to the protein-free diet in quantities equivalent to 4 mg/nitrogen/day results in an immediate reduction in the total nitrogen excreted by all experimental groups, but particularly by the low fat-low calorie rats, and thence to a decrease in the negativity of the nitrogen balance. The concentrations of urea nitrogen in the urines of both groups fed 14 Calories drop concomitantly (fig 10). There is a fall in the

excretion of ammonia when methionine supplements the low fat diet, but not when it is added to the rations of rats receiving the restricted amount of the high fat diet. That despite the marked decrement in total urinary nitrogen the relative proportion of ammonia to urea nitrogen in the urines of the rats fed 14 Calories of the low fat diet remains the same as it was before the methionine was administered, suggests that methionine plays its part in regulating the process, whatever it is, that catalyzes the catastrophic breakdown of body tissue.

Fig 10 EXCRETION of urea and ammonia by rats fed protein-free diets supplemented with methionine and providing 14 Cal/day/300-gm rat

On the basis of the discussion today, nitrogen retention represents the interaction of many factors, i.e. caloric value of the diet, source of non-protein calories in the ration, physiological state, body stores, individual resistance, quantity of dietary protein particularly in relation to the energy value of the diet, the time factor, and the distribution of animal protein over the day's meals. Only when the influence of these and probably other factors in the establishment of nutritional state in man is fully understood will it be possible to state his protein requirements in terms of practical recommendations.

EXTRA CALORIC FUNCTION OF DIETARY COMPONENTS IN RELATION TO PROTEIN UTILIZATION¹

ERNEST GEIGER

*From the School of Medicine, University of Southern California, Los Angeles and
Van Camp Sea Food Co, Inc, Terminal Island, California*

"Interpretations based on single factor relations do not adequately take into account the multiplicity of other factors, both in the organism and in the experimental diet, which obviously condition the results of the experiment"

J and TH GILLMAN²

A NECESSARY requirement for the utilization of dietary proteins and amino acids in growth and maintenance is the availability of all essential nutrients in the body. Deficiencies of vitamins, minerals, or any other essential food elements usually result in cessation of growth, loss of weight and a negative nitrogen balance. Since all the 'essential' food elements are normally supplied by the diets, a discussion of the effect of dietary composition on amino acid utilization would comprise practically the whole territory of intermediary metabolism, which is beyond the scope of this paper.

We will rather discuss more specifically the effect of those food ingredients which are fed simultaneously or within a short interval of time before or after consumption of the proteins.

The sparing effect of dietary fat and carbohydrate on protein utilization was recognized early and was explained by the concept of *isodynamism*. The idea that dietary carbohydrate may have a specific effect on protein utilization in addition to its calorogenic action was often hinted in the early literature concerning the dietotherapy of diabetes. Rose (1), in his fundamental paper on essential amino acids, stressed as early as 1937 the point that, "factors such as the proportion of fat and carbohydrate in the ration may play important roles in determining the

minimum level of a given component," i.e., essential amino acid.

Since that time several investigators indicated the existence of a specific effect of dietary components on the utilization of amino acids and proteins.

In recent studies on the development and possible nutritional improvement of meal patterns, we investigated the importance of time relations in the consumption of different food ingredients. In confirmation of earlier experiments (2), we found that the nitrogen-sparing effect of carbohydrate depended on the time which had elapsed between the feeding of the protein moiety and the carbohydrate moiety of the diet. When sugar had been fed more than four hours before or after the protein meal, no nitrogen-sparing effect could be observed.

In well-fed *adult* rats, the nitrogen-sparing effect could be demonstrated during the first few days only, after which time the nitrogen balance, in spite of subsequent simultaneous feeding of sugar, returned to its original level, probably because of the inability of the adult organism to store abnormally high amounts of protein. Further investigations on *growing* rats as well as on *protein-depleted adult* animals in which increased and prolonged protein demand existed demonstrated that both the growth response in infant animals and the repletion in depleted adults was superior when sugar was given simultaneously with protein, as compared with control animals which received sugar and protein separately, the total caloric intake being identical in both instances. In these latter experiments the nitrogen-sparing action of sugar lasted not only for 2 to 3 days, but for the duration of the experiments, i.e., 14 to 21 days (3). These results indicate that dietary nitrogen-containing

¹ The unpublished experiments discussed in this paper were performed in collaboration with I. El Rawi, E. B. Hagerty and L. E. Geiger. The experiments have been supported by grants from the National Vitamin Foundation, the Williams Waterman Fund of the Research Corporation and by the Van Camp Sea Food Co., Inc.

² In *Human Malnutrition*. New York: Grune and Stratton, 1951.

compounds when fed simultaneously with carbohydrates are retained and utilized for growth and repletion, i.e., they do participate in normal protein metabolism.

Such simultaneously fed sugar or any other dietary ingredient may *a priori* influence the protein utilization at one or all of the three following phases: in the gastrointestinal phase, in the phase of body protein formation and in the metabolic phase.

in growth promotion, had to be investigated. Consequently, *adult* male rats were induced to eat spontaneously definite quantities of either skim milk or a standard casein powder or one of the strained meats. Two, four and six hours later the nitrogen in the stomach and intestinal content was determined. We were surprised to find that the milk protein disappeared much more slowly from the digestive tract than any of the other proteins tested. Our thinking has been

TABLE 1. GASTROINTESTINAL ABSORPTION OF NITROGEN-CONTAINING COMPOUNDS

MATERIAL FED	CONSUMED NITROGEN ABSORBED AFTER				RESIDUE AFTER TWO HOURS	
	2 hr	4 hr	6 hr	8 hr	In stomach	Intestines
	%	%	%	%	%	%
Skim milk, spray dried	18.3	36.9	59.3	79.2	91.5	8.5
Whole milk, spray dried	22.0	53.3	70.3		94.0	6.0
Fish ¹	55.7	71.2	92.2	93.6	80.4	19.6
Pork	36.5	63.6	85.6	92.0	79.7	20.3

Lactalbumin	31.8	66.7	83.8		60.0	40.0
Fish ¹ plus 0.66 gm glucose	27.4		79.0		69.3	30.7
Fish ¹ plus 0.66 gm cellulose	55.7				74.5	25.5
Casein plus 0.6 gm glucose	37.5	73.1	99.0		81.0	19.0
Casein plus 0.8 gm lactose	32.0				93.0	7.0
Casein plus 0.6 gm cottonseed oil	15.8		54.6		78.0	22.0
Casein plus 0.6 gm sucrose	43.0		97.0		88.5	11.5
Casein digest ²	89.4	93.0			1.0	99.0
Casein digest ² plus 0.6 gm glucose	81.6				29.0	71.0
Casein digest ² plus 0.4 gm cottonseed oil	71.4				73.0	27.0
Zein	40.0		46.0		2.0	98.0
Gelatin	72.0				5.0	95.0

The different proteins were fed in quantities containing approximately 100 mg nitrogen to adult male rats, after 24 hours' starvation. Experiments with casein, zein and gelatin indicate that gastric emptying time is dependent on some characteristics of the protein.

¹ Strained tuna

² Spray dried acid hydrolysate fortified with tryptophan

The importance of the gastrointestinal phase in this respect was suggested by some experiments in which the nutritive value of commercial 'strained' meat products was investigated, using as a standard spray-dried skim milk. We found that diets containing skim milk as the only protein source had the strongest growth-promoting effect on infantile rats, the next best effect was obtained with diets containing strained tuna, while strained beef, pork, veal and lamb proved to be less effective.

Since the amino acid inventory of these proteins is nearly identical, the possibility that some differences in the digestibility of the proteins used could account for the observed differences

conditioned by the rather unsubstantiated claim that 'easily digested, easily absorbed' proteins are nutritionally superior to the others. Therefore, the result of this investigation, indicating that the protein source which promoted growth best disappeared most slowly from the digestive tract, was unexpected (see table 1).

We should consider, however, that the growth rate is determined by inherent regulatory factors and is not accelerated by superoptimal supply of the building stones. Tissue protein synthesis, and hence growth, requires the *simultaneous* presence of all the amino acids. Evidently the dietary proteins are best utilized for growth when the rate of supply from the digestive tract corre-

sponds closely with the growth requirements. When the rate is too fast, the utilization will suffer because no excess of amino acids can be stored normally for later use, the surplus is either excreted or irreversibly metabolized (4, 5). Therefore, a delay in the protein digestion and absorption should tend to improve the utilization. Such a mechanism is suggested also by the investigation of Leverton and Gram, as well as Wu and Wu (6, 7). Their experiments on adult human beings indicate that the utilization of dietary protein improves when intake and resorption are evenly distributed throughout the day by consuming more frequent protein meals.

We recently found that lactalbumin, which supports growth to a higher degree than casein, disappears more slowly from the intestinal tract than does casein. This observation seems to favor the outlined ideas.

Experiments prompted by such considerations revealed that simultaneous consumption of sugar does delay the disappearance of protein and absorption of its cleavage products from the digestive tract, suggesting that the delay in the intestinal resorption may well be involved in the nitrogen-sparing action of sugar fed simultaneously.

Further experiments have shown that in accordance with the classic observations of Ewald and Boas (see 8) on gastrointestinal motility, simultaneously fed fat, even more than carbohydrate, considerably delayed the disappearance of protein from the digestive tract.

A similar effect of fat on resorption of another nutrient has been reported by Nief and Deuel (9), who found that the rate of intestinal absorption of galactose varies inversely with the percentage of fat present in the diet, and that fat secures a better utilization of this sugar by preventing 'galactose-flooding' of the organism.

Based on these results, the effect of simultaneous fat feeding on growth has been investigated. One group of infantile male rats received casein from 7 P.M. to 11 P.M. and a protein-free, but otherwise complete, diet from 7 A.M. to 3 P.M. Another group received the fat moiety of the diet mixed to the protein meal. It was found that the rats receiving fat with the protein grew markedly better than the controls, although the total caloric and protein intakes were identical (see fig. 1).

The proper balance between rate of supply and rate of utilization seems to be even more critical in feeding amino acid mixtures than in feeding

protein. Accordingly, the growth-promoting action of carbohydrate and fat is more pronounced when fed simultaneously with a tryptophan supplemented casein hydrolysate.

The experiments discussed so far are in complete agreement with many earlier data. For example, it was reported that rats fed equicaloric diets grew better if the fat content of the diet was increased (10, 11). The protein digestion was improved, the nitrogen retention increased, and the fecal and urinary excretion of some essential amino acids, such as valine, lysine and methionine, was less on diets containing corn oil than on a fat-free diet.

These effects could be explained by the observation that simultaneously fed fat generally delays the intestinal passage and thus improves

Fig. 1 EXPERIMENTS in which the protein moiety of the diet was fed either separately or together with sugar or fat. Infantile male rats of the Wistar strain were used. Each group contained 8 rats with a starting weight of 50 to 55 gm.

digestion of the protein and the absorption and utilization of amino acids.

This explanation is, however, at variance with the results of some other authors (12, 13), who found that an increase of the fat content of the diets which were kept isocaloric with the control diet promotes growth without affecting nitrogen retention.

Munro has shown, furthermore, that fat, unlike sugar, when fed simultaneously with protein, fails to increase nitrogen retention in adult rats. In view of our experiments with carbohydrate, we investigated the effect of simultaneously fed fat on the repletion of protein-depleted rats and found that, contrary to the effect of sugar, simultaneously fed fat did not increase nitrogen retention.

However, it should be emphasized that our results cannot be compared directly with those of some earlier authors since the daily fat intake in our experiments was not changed—the same

amount of fat was fed either apart from or together with the protein moiety of the diet.

We believe that in addition to its action on gastrointestinal resorption, fat also exerts an effect on protein utilization at some other level. It has been reported (10, 11) that animals kept on protein-free, isocaloric diets, lose less weight if the fat intake is kept high. Evidently the high fat intake decreases also the catabolic destruction of body tissue. Furthermore it was reported that the damaging effects of excessive methionine doses can be antagonized by increasing the fat content of the diet.

These experiments would indicate that although simultaneous fat intake improves protein utilization by retarding the rate of amino acid supply from the digestive tract, its total effect must be much more complex.

Returning to the protein-sparing action of carbohydrates, it was found that although the retardation of absorption is smaller than in the case of fat, the growth promotion and the nitrogen-sparing effect are much more pronounced when carbohydrate is fed simultaneously with protein instead of fat. This indicates that the effect on absorption is only a minor factor involved in the protein-sparing action of sugar.

Following the fate of food constituents after transfer from the digestive tract to the body proper, they may affect the utilization of the absorbed amino acids in the process of tissue protein synthesis. Since protein synthesis requires the simultaneous presence of all the constituent amino acids, the most obvious effect of sugar seems to be the provision of precursors for the formation of missing nonessential amino acids. This possibility was investigated in collaboration with Dr. Arne Wick (14) by feeding C^{14} -labeled sugar and ammonium phosphate to growing or protein-depleted rats, together with or apart from Rose's mixture of essential amino acids. It was to be expected that if the sugar is utilized for amino acid formation and thus supports the protein utilization, more labeled material will be taken up by newly formed or repleted tissue. The results obtained on normal adult rats do not substantiate this hypothesis, although the error of the procedure may still mask possible differences. Experiments are now in progress in which the uptake of labeled carbon by the protein formed during liver or plasma regeneration is investigated. These recent studies show that protein isolated from the regenerating liver tissue contains considerably more C^{14} when

sugar and essential amino acids are fed together. This supports the hypothesis that simultaneously fed sugar promotes protein synthesis by providing the necessary precursors for the synthesis of nonessential amino acids.

Recently published experiments (15) in which more nitrogen was retained by the body if ammonium salts were fed together with sugar than without sugar also seem to indicate that simultaneously fed sugar may expedite the utilization of nitrogen used for amino acid synthesis.

The conditions are still more complicated in growth where the formation of new tissue requires probably, besides the necessary amino acids, also the simultaneous availability of other cell constituents. How far a fast-growing organism can draw on reserves of such factors as minerals, etc., if they are missing from the diet has not yet been investigated.

That some of the nutrients such as vitamins once deposited in the tissues are no longer easily available can be demonstrated by feeding to vitamin-depleted rats tissues of their equally depleted litter mates. The result is usually a dramatic improvement. We therefore investigated whether growth of rats is influenced when the water-soluble vitamins are fed simultaneously with or apart from the protein-containing diet and found that in some experiments the growth was definitely improved when the vitamins were fed simultaneously with the diet, while in others there was no apparent difference. However, the rats receiving the vitamins separately from the diet never grew better than the others. For all practical purposes the growth was the same on meals containing vitamins or with later vitamin supplementation.

That the feeding of some minerals in proper concentration may improve the utilization of dietary proteins has been recently proposed by McQuarrie and Ziegler (16). These authors reported that by balancing the phosphorus and calcium content of the diet the biological value of meat products can be raised to that of milk. We repeated the latter experiments, adjusting the calcium and phosphorus content of all the diets to values equal to the milk diet. In spite of this, the efficacy of the diets was the same as in the control experiments. The growth on milk was best, then strained tuna, beef, followed in order (fig. 2).

We are still at a loss to explain the reason for the differences between the results of the Minneapolis group and ourselves. However, our experi-

ments show that equalizing the P, Ca, Mg and K content in itself does not raise the biological value of the meat diets to that of the diet containing milk protein

How the intake of precursors or of substances promoting the formation of cell constituents such as lipids, certain carbohydrates and nucleoproteins influences the amino acid utilization has yet to be investigated. One perhaps may object that the organism with intact lipo- and glyconeogenic faculties is able to form such compounds itself and does not depend on dietary supply. Such objections usually result from a misinterpretation of Schoenheimer's fundamental concept of 'dynamic equilibrium' and from the

Fig 2 GROWTH EXPERIMENTS with diets containing equal amounts of calcium, phosphorus, magnesium and potassium. Each group contained 6 male rats of the Long Evans strain

indiscriminate use of the term 'metabolic pool'. It has been, therefore, assumed erroneously that it is irrelevant whether substances like sugar have been produced in the intermediary metabolism or were provided with the diet. In the first place, it is questionable whether or not such substances produced in the body can be supplied at a rate optimal for tissue synthesis.

Evidently a substance carried in high concentration by the portal system from the digestive tract to the liver has a different effect and fate than when produced in the tissues. For instance, absorption of dietary sugar increases the insulin production and also activates the anterior pituitary gland (17, 18). It has been shown that both hormones improve protein utilization (19). We investigated whether such increased hormone production could be held responsible for the nitrogen-sparing effect of simul-

taneously fed sugar. In these experiments diabetic as well as hypophysectomized animals reacted like normal rats so that the Langerhans islands and the anterior pituitary play no major role in the nitrogen-sparing action of sugar.

The third point at which dietary constituents may exert their influence on protein utilization is the 'metabolic phase,' comprising formation, destruction and transformation of amino acids.

A specific action of fat on the utilization of cystine was reported by Salmon (20) who also found that the nicotinic acid requirement is decreased in fat-rich diets. This latter effect may spare some tryptophan and divert it to other metabolic pathways.

The problem in which we are particularly interested at the present time is how sugar may exert its action on amino acid utilization in this metabolic phase. One possibility under investigation is that the simultaneous resorption of sugar protects the circulating amino acids from premature deamination in the liver. This possibility is supported by the experiments of Krebs (21) who found that the deamination by liver slices *in vitro* is decreased in the presence of easily oxidizable material such as lactate, pyruvate, etc. The decreased specific dynamic action of protein when fed simultaneously with sugar also suggests protection against catabolic changes.

It is likewise possible that some preliminary steps for protein synthesis, such as acetylation or phosphorylation is promoted by simultaneously fed sugar. This hypothesis is supported by Miller's (22) experiments in which it was found that the uptake of labeled lysine during liver perfusion is promoted by sugar.

SUMMARY

We tried to demonstrate that dietary substances fed together with proteins do promote growth and utilization of the dietary amino acids, quite apart from their calorogenic sparing action. Of course, some of our conclusions are still open to objections and will have to be supported by further experiments. Especially, the effect of parenteral administration of fat and sugar will have to be investigated.

We believe that besides the effect on intermediary metabolism, special attention should be given to the effect of food ingredients on gastrointestinal dynamics, including motility, gastric emptying time, as well as the effect on the production of bile and other digestive juices.

and, finally, on their influence on rate of digestion and absorption

We have discussed mainly factors which promote protein utilization but it is known that some ingredients such as cocoa (23) may interfere with protein digestion and with the efficiency of its utilization

The possibility should not be overlooked either that some effect may be produced by the food ingredients tested indirectly by influencing the bacterial flora (24)

We did not discuss the mutual effect of different dietary proteins and amino acids on their

utilization, although the phenomena of supplementation and amino acid imbalance may also be influenced by the presence of other factors in the meal

It is unknown how far the reported findings on animals are applicable to human nutrition. Therefore we refrain from drawing practical conclusions at the present time. We are convinced, however, that the indicated lines of study may eventually lead to a scientific planning of meal patterns with an optimum utilization of available protein resources

INTERPRETATION OF NITROGEN BALANCE DATA

JAMES B ALLISON

From Rutgers University, New Brunswick, New Jersey

RECENTLY, Mitchell (1) has presented an excellent outline of protein metabolism which is based on Folin's (2) concept of two distinct types of metabolism but includes later developments, particularly those of Whipple (3) and Schoenheimer (4) and their associates. This outline accepts the principle that endogenous metabolism represents irreversible reactions involving tissue proteins and other nitrogenous constituents as typified by the dehydration of creatin to creatinine. Exogenous catabolism could be defined as catabolism of nitrogenous constituents in amounts exceeding the needs of the animal for endogenous maintenance and growth. Dietary and body nitrogen may be said to meet in a common metabolic pool of blood and tissue proteins, a pool that can be drawn upon for either exogenous or endogenous purposes. Exogenous catabolism could include, therefore, the utilization of dispensable stores of body proteins, stores which have been described as being raided for specific amino acids not supplied in the diet (3, 5, 6).

The depletion of body protein stores is reflected by a decrease in excretion of urinary nitrogen. When an animal is placed on a protein-free diet, urinary nitrogen excretion decreases, rapidly at first, then more and more slowly. This initial rapid loss of nitrogen represents the catabolism in part of labile protein stores. After these stores are depleted the loss of nitrogen is less rapid, urinary nitrogen excretion approaching a low and constant value (fig. 1). It is interesting to note that, during regeneration, accomplished by feeding protein, those nitrogen stores that are depleted last are probably refilled first. These results suggest that the stores depleted last are more essential and are replenished before those which are dynamic and dispensable (7).

A better understanding of nitrogen stores can be obtained, however, from nitrogen balance than from urinary nitrogen excretion. Nitrogen balance (B) is the difference between dietary nitrogen intake (I) and nitrogen excreted in the feces (F) and urine (U) so that

$$B = I - (F + U) \quad (1)$$

The animal is gaining nitrogen when B is positive, it is losing nitrogen when B is negative, and it is in nitrogen equilibrium when B is zero.

The relationship between nitrogen balance and nitrogen stores is illustrated in figure 2. These results were obtained by feeding alternately a protein-free diet and one containing protein to a dog (8). The white bars record the nitrogen balance during the protein-free period, while the bars with slanted lines represent the balance while the animal was receiving a constant nitrogen intake. The magnitude of the protein stores of this dog was average, resulting in a negative nitrogen balance of -2.4 gm of nitrogen/day/m² of body surface area (first white bar). Protein was added to the diet, but not sufficient protein to put the dog in nitrogen equilibrium. Continued negative nitrogen balance resulted in further reduction in the catabolism of body stores so that, when the animal was returned to the protein-free diet (second white bar), the urinary nitrogen excretion was reduced still further and the nitrogen balance was less negative. Continuation of this type of alternate feeding resulted eventually in depletion of the protein stores to such an extent that the amount of nitrogen being fed produced a positive balance. Thus, nitrogen balance is a variable, changing with time as the protein stores are increased or decreased.

The relationship between nitrogen intake and balance is illustrated by the curves in figure 3. It is assumed that the data for these curves were determined over a short period of time, so that nitrogen balance was not altered significantly by continued feeding of nitrogen. Curve A was obtained by feeding whole egg protein to a dog depleted in protein stores. The low stores are demonstrated by the relatively low negative balance of -1 gm of nitrogen/day/m² of body surface area. A small amount of dietary nitrogen was required to maintain nitrogen equilibrium in this animal. The curve extends far into the region of positive balance, showing marked capability on the part of the animal to fill depleted stores. A maximum was reached at approximately

+6 gm of nitrogen/day/m² surface area. Curve C illustrates data obtained while feeding the same protein to a dog with full protein stores. The fullness of the stores is reflected by the balance of -4 gm/day/m² surface area and by the relatively large quantity of dietary nitrogen necessary to maintain nitrogen equilibrium. Since the stores of this dog are essentially full, only a slight positive nitrogen balance was produced. The degree of depletion of the stores in an animal can be estimated by the magnitude of positive balance which is produced by a given nitrogen intake.

Fig 1 URINARY NITROGEN EXCRETION (gm/day/m² body surface area) in a dog fed a protein-free diet for 50 days

Curves B and D represent data obtained while feeding wheat gluten instead of whole egg protein. The rate of increase of nitrogen balance with nitrogen intake was less with wheat gluten than with whole egg in the diet, and the maximum positive balance was also less. The nutritive value of the dietary proteins can be measured in terms of the slopes of the lines in figure 3, and by the maximum positive balance which can be produced.

The curves in figure 3 are essentially linear until the point of maximum utilization is reached. The relationship, therefore, between nitrogen balance (B) and absorbed nitrogen (I) can be expressed by the following equation

$$B = KI + B_0 \quad (2)$$

where K is the slope of the line and B_0 is the

balance when the nitrogen intake is zero. This equation may be rewritten to eliminate nitrogen balance as follows

$$U = (I - K) I + U_0 \quad (3)$$

Fig 2 NITROGEN BALANCE (gm/day/m² body surface area) in a dog fed a protein-free diet (white bars) alternately with diet containing 0.9 gm of egg white nitrogen/day/kg body weight (bars with slanted lines)

Fig 3 NITROGEN BALANCE vs absorbed nitrogen in a protein-depleted dog fed whole egg protein (A), in a protein-depleted dog fed wheat gluten (B), in a normal dog fed whole egg (C) and in a normal dog fed wheat gluten (D)

where U is the excretion of urinary nitrogen during nitrogen feeding and U_0 is the excretion of urinary nitrogen on a protein-free diet (9). It

has been proven (9, 10) that K in these equations is the fraction of absorbed nitrogen retained in the body of the animal, provided the excretion of body nitrogen (B_0 or U_0) is constant over the whole range of nitrogen intakes. The fraction of absorbed nitrogen retained in the body is by definition the 'biological value' (11) of the protein. The slope of *line D* is 0.4. If body nitrogen excretion is constant, then 40 per cent of the wheat gluten nitrogen was retained in the body of the animal. It was pointed out in the introduction, however, that dietary and body nitrogen may enter a common pool which is available for catabolism as well as anabolism. It is not surprising, therefore, to find evidence that feeding nitrogen may decrease or increase the contribution of body nitrogen to catabolism.

Fig 4 AVERAGE DATA obtained on dogs fed protein-free diet (*white bars*) and protein-free diet plus 1 gm of *dl*-methionine per day per dog (*bars with slanted lines*)

The conservation of body nitrogen by dietary nitrogen has been demonstrated by feeding methionine to dogs (12-14) and to rats (15). The excretion of urinary nitrogen in the dog is decreased by adding a small amount of methionine to a protein-free diet (fig 4). Less body nitrogen is contributed to the catabolic pool in the presence than in the absence of methionine. It has been suggested (16) that the demands for methionine in the dog are relatively great so that body protein reserves are utilized to supply this amino acid, the excess catabolism of nitrogenous constituents thereby contributing to an increased excretion of urinary nitrogen. Mitchell (1) has suggested that the extra demand for methionine is the result of the growth of hair at the expense of other tissues of the body, the hair demanding large amounts of sulfur amino acids. Addition of

an optimal amount of methionine to some proteins such as casein can increase the value of K in *equation 2* to values over unity. Values over unity would be impossible if B_0 in the equation represented the excretion of body nitrogen at all nitrogen intakes. Values over unity can be interpreted to mean that feeding nitrogen reduces catabolism of the nitrogenous constituents in the metabolic pool. Swanson and coworkers (14) have given several other examples of the nitrogen-sparing action of dietary nitrogen in the rat.

Dietary nitrogen may also increase the utilization of the nitrogen in the body pool. A large amount of methionine (5%) in a diet containing casein when fed to the rat increases the catabolism of these stores (17). The data suggest, too, that the metabolism of excess methionine requires the simultaneous catabolism of fat (18) and of the utilization of the amino acid glycine (19). Excess methionine may draw on the nitrogen pool for glycine, thereby causing increased catabolism of other amino acids in the pool. Addition of glycine together with methionine reduces this excess catabolism. The beneficial effects of glycine may be due to the participation of this amino acid in the catabolism of methionine, glycine being the precursor of serine. One pathway for the metabolism of methionine is by the way of a combination of homocysteine and serine to form cystathionine (20-22). Other examples of raiding of nitrogen stores have been suggested by the work of Whipple and associates (5, 6). They have found that blood proteins can take priority over other tissue proteins, that depleted dogs will continue to produce much plasma protein and hemoglobin for many weeks while being fed a low nitrogen diet. An inadequate protein-like globin, or an inadequate mixture of amino acids can result in formation of blood proteins, other tissue proteins possibly being depleted to supply the deficient amino acids (23).

Since K in *equations 2* and *3* need not be equal to 'biological value,' this constant has been called the nitrogen balance index of the dietary protein (24). The index is a function of the fraction of nitrogen retained in the body of the animal. It is more specifically the rate of change of nitrogen balance with respect to nitrogen intake, and it is a relative measure of the amount of nitrogen necessary to maintain equilibrium, a measure of the over-all utilization of nitrogen by the animal.

Table 1 records nitrogen balance indexes for six standard proteins or protein foods in adult dogs. These data were obtained from experiments which were a part of a cooperative study of protein evaluation sponsored by the Bureau of Biological Research of Rutgers University. The effects of supplementing casein with methionine and wheat gluten with lysine on the nitrogen balance indexes are illustrated in the table.

The index for whole egg protein in adult dogs is usually found to be equal to or better than egg white. The relatively low index for whole egg protein recorded in table 1 is believed to be associated with changes produced during processing and drying of this particular whole egg preparation. It is interesting to compare these indexes

with those obtained in other studies. Variations in technique and in the physiological state of the animal. Some of these variations will be mentioned in the following discussion.

The index for raw egg white was found to be abnormally low in one so-called normal dog. This low value was associated with poor digestibility which could be attributed to the antitryptic factor in raw egg white. Poor digestibility of raw egg white was found also in most dogs depleted in protein stores (7). Morgan *et al* (25, 26) have found the dog, particularly the puppy, to be vulnerable to this antitryptic activity of egg white.

Nitrogen balance indexes all tend to increase when the protein stores of the dog are depleted markedly. Indexes, for example, in protein-de-

TABLE 1 AVERAGE DATA OBTAINED ON SIX DOGS

PROTEIN SOURCE	ABSORBED NITROGEN I	URINARY NITROGEN U	PROTEIN EFF. URINARY NITROGEN U ₀	NITROGEN BALANCE INDEX E
	<i>gm/day/m²</i>

Peanut flour	4.22	3.74	1.89	0.56
Wheat gluten	3.01	3.09	1.11	0.44

The nitrogen balance indexes were calculated from equation 3 in the text.

¹ Average on 3 dogs.

with some determined several years ago on different samples. These earlier determinations yielded the following indexes: casein plus methionine, 1.2; egg white, 1.0; beef, 0.85; casein, 0.80; and wheat gluten, 0.44 (8). The casein with the index of 0.80 was a cruder sample than the one with the index of 0.73 (table 1) and probably had a higher methionine content. The beef sample with the index of 0.85 was selected from the best cuts of meat while the sample listed in table 1 was representative of all types of beef protein. These indexes for beef in the adult dog are much higher than values reported by Morgan *et al* (25), a difference which emphasizes the susceptibility of the nitrogen balance method to varia-

Fig. 5 NITROGEN BALANCE/nitrogen intake in puppies fed 25 per cent casein diet beginning at time of weaning (8 weeks).

pleted dogs were found to be as follows: egg white, 1.12; whole egg, 1.06; casein, 0.84; and wheat gluten, 0.70 (7). In general, however, indexes are essentially constant and independent of the magnitude of the protein stores until those stores have been depleted markedly. Nitrogen balances, on the other hand, vary with time, the animal always drifting toward equilibrium if the balance is either negative or positive. In this way the stores are depleted or repleted to a point of equilibrium if the balance is either negative or positive. In a growing animal, fed an adequate protein, the positive nitrogen balance per gram of nitrogen intake decreases rapidly as the animal approaches adulthood, a decrease which is illustrated in figure 5. Nitrogen balances per gram

of nitrogen intake have been found to have greater significance as measures of protein utilization in the growing dog than the customary protein efficiency (grams gain in weight/gram of nitrogen intake) The data in table 2 compare nitrogen balance with body weight gain data for the evaluation of dietary proteins in beagle puppies These data were calculated over a period of

TABLE 2 AVERAGE INCREASE IN BODY WEIGHT PER GRAM OF NITROGEN INTAKE BW/I AND AVERAGE POSITIVE NITROGEN BALANCE PER GRAM OF NITROGEN INTAKE I/B IN THREE BEAGLE PUPPIES DURING FAST-GROWING PERIODS (15)

Fig 6 White bars represent nitrogen balances in a dog fed a protein-free diet before and after repletion. Circles represent positive nitrogen balances produced while repleting with a constant intake of whole egg protein

several weeks of the fast-growing period of the animal

These data demonstrate that weight gains are not as accurate a measure of the utilization of a protein as nitrogen balance. The puppies fed wheat gluten increased their caloric intakes above those receiving whole egg. They became fat and soft, while those fed whole egg became lean and hard, but both sets of dogs weighed about the

same after 70 days on the respective diets. Growth of the protein stores, however, was much greater in the dogs fed whole egg than in those receiving wheat gluten.

Positive nitrogen balances decrease in depleted adult dogs fed a constant nitrogen intake. This gradual drop in nitrogen balance is illustrated in figure 6. The first bar in negative balance records the excretion of nitrogen on a protein-free diet. The gradual drop in positive balance during the protein-feeding period can be interpreted to be a reflection of increasing protein stores. The increased catabolism of these stores is illustrated by the greater negative balance obtained while feeding a protein-free diet following the repletion period (second white bar). Similar experiments using wheat gluten have demonstrated that, even after prolonged feeding of this protein, the balance on a protein-free diet is often not made more negative, but may even be more positive. These results suggest that wheat gluten may deplete some protein stores to aid in the repletion of others (7).

The proteins of the body and nitrogen balance can be effected also by the caloric intake (27). Recent experiments in dogs demonstrate that the nitrogen balance decreases regularly as the caloric intake decreases. Data in table 3 were obtained on dogs receiving a constant nitrogen intake of 3.82 gm of casein nitrogen/day/m² of body surface area. As the caloric intake was reduced, the nitrogen balance decreased from +0.68 to -0.74. Measurements of nitrogen balance were taken over a short period of time, so that the protein stores of the body were not markedly altered by prolonged feeding. Other experiments (26) demonstrated that the nitrogen balance index was not altered initially by the decrease in calories. Curves such as those illustrated in figure 3 were shifted downward farther into the region of negative balance but without altering their slopes. The values for B_0 in table 3 illustrate this shift into negative balance. These values were calculated using an average index of 0.73 for casein determined over short feeding periods for all caloric intakes except the very lowest of 95 calories/day/m². These results suggest that restriction in calories increases the catabolism of exogenous reserves of both body and dietary nitrogen. The increased catabolism, however, does not alter at first the mechanism of filling these stores as measured by the nitrogen balance index. When the more labile body stores are re-

duced, however, the index decreases rapidly, essential tissues are depleted, and irreversible damage may be done if the caloric restriction is continued. It has been demonstrated that animals with adequate body protein reserves can resist the depleting effects of a caloric restriction over long periods of time while those with inadequate stores rapidly deteriorate. The rapid deterioration is illustrated by *curve A* in figure 7. *Curve A* represents data obtained on a dog partially depleted in protein so that 3.82 gm of casein nitrogen/day/m² and 480 calories/day/m² produced a positive nitrogen balance. In the absence of abundant labile protein stores, the index was immediately reduced and the ani-

was always associated with the drift into negative balance following a restriction in calories. It should be emphasized that these data were obtained on dogs being fed a low fat diet containing a quantity of casein which maintains the average dog on an adequate caloric intake in nitrogen equilibrium. The response to a caloric restriction is a function of the balance between dietary constituents as well as of the physiological state of the animal. Further evidence for the importance of the balance between calories and proteins is found in the work of Schwimmer and McGavack (28), who demonstrated that young men fed a low nitrogen intake (3

TABLE 3 AVERAGE VALUES FOR CALORIC INTAKE AND NITROGEN BALANCE (B) FOR THREE DOGS FED 3.82 GM CASEIN NITROGEN/DAY/M² OF BODY SURFACE AREA

480	-0.22	3.00
95	-0.74	

Protein-free nitrogen balances (B₀) were calculated assuming an index of 0.73 (27).

mal drifted rapidly into negative balance. Nitrogen integrity of the body could not be maintained in this animal at a low caloric intake even with nitrogen in the diet. *Curve B* represents data obtained on another dog with large protein stores, so that 3.82 gm of casein nitrogen/day/m² and 480 calories/day/m² were not sufficient to put this animal into positive balance. Prolonged feeding depleted these stores, the dog approached nitrogen equilibrium, but because of the low caloric intake eventually drifted into a period of rapid loss of nitrogen. Thus *dog B* resisted the damaging effects of caloric restriction over a longer period of time than *dog A*. Indeed, until *dog B* began to drift rapidly into negative balance, this animal was alert and seemed to be in good clinical condition. Loss of interest in daily routine, irritability and marked weakness

Fig 7 NITROGEN BALANCE (gm/day/m²) vs days of feeding a reduced caloric intake (480 calories/day/m²) and a constant nitrogen intake of 3.82 gm casein nitrogen/day/m². *Dog A* was partially depleted in protein stores at the beginning of the experiment, *dog B* had adequate stores.

gm egg white nitrogen/day) did not retain dietary nitrogen until the caloric intake had been increased to 1500 calories. If the intake was increased to 6 gm/day, the nitrogen was retained at a much lower caloric level (900 calories). Bosshardt *et al* (29) demonstrated that an increase in calories at a constant protein level improved the utilization of protein, which was enhanced still further by the addition of more protein. The authors suggest that protein is the most important limiting factor in many states of semi-starvation.

Data in the literature suggest that fat in the diet exerts a role over and beyond the provision of calories, possibly through an effect on protein metabolism. Swanson and collaborators (30),

studying the effect of nitrogen excretion in low nitrogen diets, reported that "the catabolism of rats, ingesting isocaloric quantities of high fat and low fat rations, proceeded at essentially the same rate. However, upon adjustment of the energy value of the diet to one-fourth of the customary caloric consumption, the elimination of fat doubled the destruction of body tissue." Schwimmer and McGavack (28) found that a diet of 900 calories, containing 30 per cent fat and 6.0 gm of nitrogen daily, decreased the urinary excretion of nitrogen in men below the excretion when the diets provided 10 and 20 per cent fat. They believed that "the nitrogen-sparing effect of 30 per cent fat was not due to increased calories, but rather to something intrinsic in the higher fat per se."

The balance between protein and calories is very important for the maintenance of normal tissues. Diets, for example, which are relatively high in calories but low in quantity and quality of protein will deplete the dispensable protein reserves of the animal, produce a fatty liver and fill the fat depots of the body. Rats, for example, fed 120 calories of a protein-free diet per kg body wt developed livers with an average of 1.1 gm of protein and 57 per cent fat. Littermates fed the same caloric intake but with 10 per cent protein developed livers with an average of 1.86 gm of protein and 28 per cent fat. Increasing the calories in the absence of protein may indeed have little conserving effect upon

body proteins, but it can have a marked conserving effect in the presence of protein. The total liver protein was increased from 1.27 to 2.30 gm as the calories were increased from 50 to 200 gm/kg body wt in animals fed a constant protein intake.

Depletion of the protein stores of the body, either through lack of calories or lack of protein or both, results in an imbalance of tissue proteins and enzyme systems which can alter the physiology of the animal markedly. The plasma albumin, for example, is depleted rapidly, but plasma alpha globulins are not (31). The succinoxidase system of the tricarboxylic acid cycle is reduced in activity, while the cytochrome oxidase system is not (32). Thus, there can be a differential depletion and repletion of many types of protein systems depending upon the physiological state of the animal and the diet. The nitrogen balance method, however, does not describe these shifts between the various protein compartments of the body, but rather measures the overall status of nitrogen retention in the animal. Nitrogen balance is the sum of the gains and losses of nitrogen from the various compartments of the body. It is possible for an animal to be in positive nitrogen balance and yet be depleting some labile stores in protein. Nitrogen balance, like body weight or growth, is the summation of many variables and the significance of the balance becomes more meaningful as those variables are evaluated.

FEDERATION PLACEMENT SERVICE

IN THE portion of the *History of the American Physiological Society*, written by Dr Charles W Greene and published in 1938 on the occasion of the semicentennial of the Society, it is recorded that as early as 1919 there was "ever-increasing discussion among Federation membership concerning the difficulties of young scientists in securing permanent positions" and reference is made to a proposed solution offered by Dr Samuel F Meltzer, a former President of the Society, to organize a "scientific information service" for which he contributed \$300 of personal funds for the expense involved for the ensuing year. This proposal was then referred to the Federation, where it was adopted as a project, the Treasurer of the Physiological Society was made custodian of the funds and Dr E E Brown of the University of Minnesota was appointed Director. As far as can be learned, Dr Brown remained in charge of the Placement Service until sometime during the 1920's, when Dr C W Edmonds assumed the duties. In 1931 Dr H B Lewis of the Department of Biochemistry of the University of Michigan became the Director, giving generously of his time and interest to the project for over fifteen years. Small sums were made available each year by assessments on the constituent Societies to cover postage and stationery, and the use of a room at the Annual Federation Meeting was arranged in 1941. Dr Lewis continued to serve until 1946, when he asked to be relieved but agreed to serve another year.

In 1947 a committee headed by Dr Philip Dow made a study of the Placement Service and recommended that 1) it be continued as a function of the Federation, 2) it be operated by the Office of the Federation Secretary, and 3) an annual fee of one dollar be paid by applicants, with the expectation that this would pay a secretary one-fourth time. This sum was soon inadequate to meet the expenses, for by 1948 they were already estimated at \$1,300 and the Federation continued to provide the funds. When Dr Milton O Lee became Federation Secretary in 1947 the records of the Placement Service were moved to Washington to the new permanent office, and all subsequent activities have been under his direction.

From these available records it is evident that the original Placement Service of the Federation of American Societies for Experimental Biology was an outgrowth of the informal placement activity of every teacher of graduate students, to whom employers and colleagues frequently write seeking likely persons to fill available positions. For more senior positions those searching for the best available candidate may gather the opinions and recommendations from a number of individuals already leaders in that particular discipline. Such methods remain extremely satisfactory where they can function effectively, but since the field of experimental biology has become extensive, the employers of experimental biologists diverse and numerous, and the number of academic departments contributing to it so large, a central source for exchange of information under the auspices of the professional societies in that field has come to meet a real need that can no longer be effectively met by unorganized efforts.

In addition, it has been convenient for candidates for positions and employers seeking personnel to meet at the Annual Spring Meetings of the Federation. Hence the Placement Service has attempted to facilitate and expedite activities already occurring, by providing a central source of information for both employers and candidates to be available at all times, and a scheduled meeting place for them at the Annual Meetings, with information of the preparation, experience, and interests of each candidate present, in a brief and standardized form which is available to all employers.

During the last few years these activities have expanded to meet the increasing needs as they have become evident. Its main function has continued to be to serve as a clearing house of factual information for both candidates and employers, with no attempt to handle references or to recommend or evaluate candidates or positions. Originally, annual lists and monthly supplements of applicants with a brief description of their qualifications and experience were sent to all employers who registered positions or who wished to be kept on the mailing list, and interviews were arranged at the annual meetings by the Director, still on a rather informal basis with very few facilities. In 1950

at the Atlantic City Meeting a new system of scheduling interviews was used with a generous floor space allotted to the Service for offices and interview booths and a staff of about twelve assistants. This proved very satisfactory and was successfully repeated in 1951 at Cleveland with a few modifications and a slightly enlarged staff.

Meanwhile, as the number of applicants increased, the method of issuing the lists of available personnel was revised. In the summer of 1950 a questionnaire was sent to all members of the American Physiological Society asking the kind of information they wished in these lists and the intervals at which it was desirable to receive them. From the returns to this questionnaire it appeared that a schedule of quarterly lists of available personnel, semiannual lists of available positions, and an annual list of available fellowships was considered by the majority to be the most useful. Such a schedule has been adopted for this year with the quarterly lists of candidates prepared in February, May, August, and November, and the lists of available positions issued in March and September. The list of fellowships was issued in April of this year but probably would best be issued in the autumn on an annual basis. There have been many requests for these new lists of available positions and fellowships.

Detailed application forms of all applicants on the list are available for study upon request by an interested employer. In addition, there are on file the application forms of a few individuals, usually with some years of additional experience, who are available but do not wish their names circulated. Obviously as there are no facilities for work with individuals, the mechanism of the circularized lists is of no help in these instances, but the information so filed has been of considerable aid to the Director in making suggestions when he has been consulted in the filling of positions requiring this additional background. In the same way a number of positions are described for the files with the request that they not be included in the publicized list. These employers prefer to retain the initiative in approaching candidates. These procedures can be retained within the framework of the present activities, but it is to be emphasized that the Service can function most effectively where there is a free interchange of information.

During the past year an addressograph-plate mailing list has been assembled of heads of

academic departments and laboratories hiring and/or training personnel in the fields of the member Societies and the circularized lists have routinely been sent to them, permitting the availability of both positions and personnel to reach a wide audience among potential candidates and employers even if they have not registered with the Service.

Such an activity becomes more expensive as its responsibilities increase and, while its value and standards can best be continued and developed under the direction of the Federation, it seems equitable that the cost should be shared by those who use it. As a step to accomplishing this, at the Cleveland Meeting in April 1951 the Executive Committee of the Federation set up a new schedule of rates, consisting of a three-

TABLE 1. APPLICANTS AND POSITIONS REGISTERED, MARCH 1950-MARCH 1951

dollar annual registration fee for candidates, and a ten-dollar subscription fee for all lists, with a five-dollar fee for any single copy. To be eligible to use the interview service at the Annual Spring Meeting an employer must be an annual subscriber to the lists or to the then current February list of applicants. It is estimated that this will provide an income to meet approximately half the cost of the Service, with the Federation supplying the remainder from its general funds. Thus the Federation will continue to direct the Service, which would be available to its membership and to non-members on much the same basis as in the past. From an over-all viewpoint the importance of this service to non-members should not be overlooked, for while it is recognized that the Service is most useful to young people just receiving their doctorate or possibly with a few years' experience, most of whom are not yet eligible for membership in the constituent Societies, the opportunity

these candidates have for performing significant research in the following few years may well determine whether or not they will become useful members of the Federation. It follows then that the Federation may thus perform a very worthwhile function not only for the individuals concerned, but ultimately for the member Societies and for the fields of scientific endeavor they represent.

A review of the records of the Placement Service especially for the past year is of interest in indicating its present and possible future usefulness, and a summary of the registrations of the year ending March 1951 are presented in table 1.

TABLE 2 APPLICANTS AND POSITIONS REGISTERED
AT CLEVELAND MEETING, APRIL 1951

	NO APPLI CANTS REGIS- TERED	NO APPLI CANTS INTER- VIEWED	NO INTER- VIEWS	POSI TIONS REGIS- TERED

Totals	209	156	532	226

In a period of expanding activity such as the present there are more positions than candidates to fill them, with accompanying competition in bidding for the services of well-prepared applicants and a consequent raising of all salary requirements and a careful selection on the part of candidates as to the opportunities presented by the position. This trend has become marked as more of the defense positions become available.

More pertinent and timely perhaps is table 2 showing the number of candidates registered at Cleveland divided into their fields of major interest. It must be pointed out that this division is arbitrary in some cases where candidates have more than one major interest or where the major interest is not included directly in the field of a member Society. In addition to the total registration, the number having interviews is recorded in column 2.

Of the 53 applicants not having interviews, about half did not register as present at Cleve-

land until the third day of registration, hence their application forms were not open to most employers when they first studied the forms. This points to a definite advantage to candidates of early attendance at the meetings.

It is interesting that a large number of biochemists, both candidates and employers, use the Service. This is not in proportion to the number of members of the Federation in that field, for while the registrations in biochemistry approximate half of the total in all six fields, the American Society of Biological Chemists has only about 70 per cent of the membership of the American Physiological Society and twice that of the American Society of Pharmacology and Experimental Therapeutics. Perhaps this is due in part to the general familiarity of all chemists with the very successful employment service of the American Chemical Society. The well-known scarcity of pharmacologists and immunologists is reflected very clearly in this table.

The positions were registered by a total of 161 employers present. Compared to the number of applicants registered, the relative number of positions does not seem to differ much from that in table 1, but a greater proportion of candidates than employers currently registered as active were present in Cleveland. Many non-member employers do not attend the Annual Meetings, while candidates seem to attend whether members or not.

To learn the qualifications of candidates which were most sought by employers at Cleveland, those receiving interviews were broken down by age groups and by degrees held. The following tables include only those for whom regularly scheduled interviews were arranged through the Placement Service.

These figures show the desire of employers for younger applicants, which is a well-recognized trend. The large number of interviews for the few applicants holding only a bachelor's degree shows a demand for trained technical assistants by these employers even though the applications of individuals not having advanced degrees have been discouraged, keeping to the policy that the Service should function chiefly on the professional level. It may also indicate that the present increase in all salary levels has forced some employers to lower their degree requirements if their funds are insufficient to meet the current range offered to candidates with advanced degrees.

Thus it would seem that the Placement Service

is meeting in a measure at least the needs of the professional group of employers is outlined above. These needs vary somewhat from the point of view of the employer and candidate.

The employer wishes objective information concerning the applicant's education and previous experience, with a chronologically complete record of his activities from the time he received his bachelor's degree, a brief account of investigative work participated in with the names of individuals under whom he may have worked, a bibliography

of published work, a list of honors received and society memberships, and the salary he expects. The employer ordinarily prefers to obtain personal references directly and to evaluate the other information himself, for employers filling positions with experimental biologists are with few exceptions prepared by experience, association and knowledge of the field to do this best.

As mentioned before, the greatest number of candidates are recent graduates and are seeking an opportunity to continue experimental work, with or without teaching responsibilities, and at a salary adequate to meet the now constantly rising cost of living. Unless the degree was ob-

tained under a department head who has few other administrative duties, many current contacts, few students and an aggressive program for placing his students, the recent graduate may not know where to look for the position he has spent so long preparing for. Once the original contact is made the candidate may not feel able to evaluate the opportunities of the position. Since it is impossible for the Placement Service to assume this function it is necessary that he seek this assistance from his older and more experienced associates.

Not infrequently older, more experienced candidates, confronted by changed conditions or by changed interests, may wish to be considered for other positions. Unfortunately in the past there has been some stigma attached to the scientist having to seek employment. The world was expected to beat a path to his door. This is not a realistic attitude in these times and it is hoped that the short factual announcements as now prepared by the Placement Service of the Federation, which is interested only in maintaining and improving the standards within the profession, can remove the reasons for this attitude and the consequent reluctance by some to utilize its service.

When positions are plentiful as now, the Service is most useful to employers. In times of scarcity of positions its usefulness to candidates is increased. At all times the more widely this information is disseminated the more opportunity there is for an applicant to accept a post for which his training and interests prepare him. Such exchange of information also tends to equalize opportunities, conditions and salaries for positions of equal rank and responsibility, requiring similar training. The list of fellowships brings together in one place the essential facts about the fellowships available in the field of experimental biology, such as place and date of application, place and conditions of tenure, requirements and stipend for the consideration of both candidates and department heads when considering their own or their students' future plans.

Since it is desired to increase the usefulness of the Placement Service in accordance with the changing needs of the individuals using it, suggestions are welcomed.

LETHA K. ANDERVONT
Assistant to the Director
Federation Placement Service

AAAS PHILADELPHIA MEETING

December 26-31, 1951

THE 118th Annual Meeting of the American Association for the Advancement of Science will include programs of all 18 of the Association's sections and of about 15 participating societies. The focus of the approximately 225 sessions will be Convention Hall, adjacent to the University of Pennsylvania's School of Medicine and its associated hospitals; there will be some meetings in the downtown hotels, especially the Bellevue-Stratford (headquarters) and the Benjamin Franklin (zoologists). Programs of particular interest to those in medicine and experimental biology include

SECTIONAL PROGRAMS

AAAS Section C—Chemistry Eleven sessions, including one on Medicinal Chemistry, *Dec 28*, two on Forensic Sciences, *Dec 29*, two on Reaction Mechanisms, *Dec 26, 27*

AAAS Section F—Zoological Sciences A symposium, "Estuarine Ecology," jointly sponsored by the American Society of Limnology and Oceanography, American Society of Zoologists, and the Ecological Society of America, *Dec 30*, a two-session symposium, "Sex in Microorganisms," jointly sponsored by AAAS Section G, the American Society of Protozoologists, American Society of Zoologists, Botanical Society of America, and the Genetics Society of America, *Dec 30*

AAAS Subsection Nm—Medicine Four-session symposium, "Aging" (with special reference to cholesterol and arteriosclerosis), *Dec 29, 30*

AAAS Subsection Nd—Dentistry Three sessions including a symposium, "Fluoridation as a Public Health Measure," *Dec 29*

AAAS Subsection Np—Pharmacy Six sessions, co-sponsored by the American Association of Colleges of Pharmacy, American College of Apothecaries, American Society of Hospital Pharmacists, and the Scientific Section, American Pharmaceutical Association, *Dec 27-29*

AAAS Section O—Agriculture Four-session symposium, "Mineral Nutrition in Relation to Plant, Animal, and Human Health," *Dec 27, 28*

PROGRAMS OF SOCIETIES

Oak Ridge Institute of Nuclear Studies Two-session symposium, "Radioisotopes in Medicine," and luncheon, *Dec 28*, a series of lectures either *Dec 27 or 29*

American Society of Protozoologists Eight sessions of papers, a luncheon, and a business meeting, *Dec 27-29*

American Society of Zoologists Fourteen sessions of papers, *Dec 28, 29*, also symposium, *Dec 27*, demonstrations, *Dec 28*, zoologists' dinner and Biologists' Smoker, evening of *Dec 29*, symposia, *Dec 30*

Herpetologists League Conference session, *Dec 28*

Society of Systematic Zoology Five sessions including breakfast, business meeting, and symposium, "Classification of Animals," *Dec 28*, two paper-reading sessions, *Dec 29*

American Microscopical Society Three sessions, *Dec 27-29*, including a symposium, "Modern Methods in Microscopy"

Biometric Society, Eastern North American Region Six sessions of papers on Biometry, *Dec 27-29*

Society for Research in Child Development and AAAS Section N Four sessions including a symposium, "Biochemistry of Nutrition in Human Growth," *Dec 27*

Alpha Epsilon Delta Premedical Honor Society Luncheon and afternoon program, *Dec 28*

American Industrial Hygiene Association Special program in connection with inauguration of the new AAAS Section P—Industrial Science

SPECIAL SESSIONS

AAAS Annual Exposition of Science and Industry The 1951 edition of the Association's Exposition again will total about 150 booths and will fill the arena of Philadelphia's Convention Hall. In addition to exhibits by leading publishers, instrument makers, and suppliers of scientific materials, there will be technical exhibits by prominent manufacturers of pharmaceuticals and biologicals. In or near the exhibit area will be the Fifth Annual International Photography-in-Science Salon and the AAAS Science Theater which, almost continuously, will show the latest foreign and domestic scientific films.

New ULTRA-THIN SECTIONING MICROTOME

THE INTERNATIONAL ULTRA-THIN SECTIONING MICROTOME is the first complete instrument developed particularly for cutting sections in the ultra-thin range. Designed to meet the exacting requirements of the electron microscopist, it is equipped with a high precision worm gear reduction feeding mechanism designed to advance the specimen in increments of $\frac{1}{20}$ micron and to permit the selection of thickness from $\frac{1}{20}$ to 1 micron. Also available is a special holder for methacrylate embedded specimens and a glass knife holder. For a discussion of the effectiveness of this instrument and the technique used see "Development and Use of the Minot Rotary Microtome for Thin Sectioning" by Geren & McCulloch, Experimental Cell Research, February, 1951.

THE INTERNATIONAL MINOT ROTARY MICROTOME, STANDARD MODEL, basically the same instrument as described above, but designed for the rapid routine

serial sectioning of paraffin-embedded specimens. Extremely accurate in construction, it is equipped with a feeding mechanism permitting sectioning in any desired thickness from 2 microns to 16 microns, in increments of 2 microns. The excellent design and precision construction of this instrument are attested by the fact that they form the basic design of the Ultra thin Sectioning Model.

INTERNATIONAL SAFETY RAZOR BLADE HOLDER. In addition to the standard Microtome knives currently available, the International Standard Model Microtome will also accommodate this Safety Razor Blade Holder. Excellent for routine sectioning, it holds the standard Gillette type Microtome blades and eliminates bothersome honing of knives. Furnished complete with screw driver, extra screws, ten blades and leather-bound box.

FEDERATION PROCEEDINGS is published quarterly by the Federation of American Societies for Experimental Biology. The *March* issue consists of the Program (Part II) of the Annual Meeting of the Federation, and the Abstracts (Part I) of the papers presented at the scientific sessions. Both parts include an author index. The abstracts are arranged alphabetically according to the first author and segregated as to Societies. The *June* and *September* issues contain symposia and other special papers presented at Federation meetings as selected by the Editorial Board. The *December* issue contains the membership list and other matters pertinent to the Constituent Societies of the Federation.

Price Schedule

The subscription price is \$4.50 (\$5.25 foreign) payable in advance. Single issues may be purchased, if ordered in advance, at the following prices: No. 1 (Part I, March, Abstracts), \$3.00; No. 1 (Part II, March, Program), 75¢; Nos. 2 and 3 (June and September), \$1.50 an issue; No. 4 (December), \$2.25 an issue. Subscriptions and orders should be sent to the Federation of American Societies for Experimental Biology, 2101 Constitution Ave., Washington 25, D. C.

Entered as second-class matter March 16, 1942, at the Post Office at Baltimore, Maryland, under the Act of August 24, 1912.

SIX-PLACE ELECTRIC STYLUS INPUT CONTROL

FOR DRY RECORDING ON
ELECTRO-SENSITIVE PAPER

For individual control of multiple
electric marking devices for mak-
ing permanent Kymograph records
without use of smoked paper or
ink

8075-C

ELECTRIC STYLUS INPUT CONTROL, Six-Place, for dry recording on electro-sensitive paper, without use of smoked paper or ink, in accordance with circuit design developed at the Merck Institute for Therapeutic Research. Provides a harmless, precisely controlled power source for producing continuous line recordings on Teledeltos paper, and can be used on practically any kymograph with minor modification.

Consisting essentially of an electronic power unit with six separate electric circuits and controls for regulating the electric current of individual styli, six removable stylus circuit leads, 6 ft long, with connecting tips and clamps, pilot lamp and on-off switch, mounted in a ventilated metal case with sloping panel and gray crystal lacquer finish.

Teledeltos paper is an electrically conducting, coated sheet developed by Western Union. Requires no preparation, developing or processing in the laboratory, and is permanently blackened where an electric current passes through the coating. Resulting records are sharp and clean and unaffected by light or atmosphere.

8075-C Electric Stylus Input Control Six-Place as above described with 5 ft connecting cord and plug, but without Teledeltos paper. For 115 volts 60 cycles, a.c. only 112 50

8018-T Paper Teledeltos Electro-Sensitive, for use with above, in rolls containing 300 ft. 15 50
Per roll, 6-inch 9 50 Per roll 10-inch

SMALL-GROUP STUDY IN A NORMALLY LIT ROOM

The image is cast upon a screen in the dark-chamber turret at table height. Each observer (up to 10) has a separate light-excluding viewing hood. The pathologist here is discussing a slide with the surgeon, the unused hoods are easily shuttered off.

LARGE-GROUP EXHIBITION IN THE DARKENED AUDITORIUM

So intense is the Scopicon light source that images up to ten feet across can be projected. Through a system of auxiliary lenses the operator can follow a biological specimen through a progressive series of ever-closer localizations, up to ultimate demonstration under oil-immersed objectives.

2 or 10 or 1000

Quickly adaptable to viewing on any scale, the mobile Scopicon couples convenience with efficiency. Its high-pressure mercury arc is the brightest light source ever employed for microprojection. The focal spot is only 1mm square (approx.). Its pinpoint character permits flickerless projection of sharply detailed images up to ten feet across even under oil-immersed microscope objectives. Let us send you the brochure describing this remarkable instrument.

**LOW COST HELP
ON WHEELS**

STAINLESS STEEL UTILITY CARTS

Ideal for Transporting Laboratory Equipment

These sturdy carts, supporting up to 200 pounds weight, find dozens of uses in the modern laboratory—save valuable time by freeing your personnel for more important work. Use them to eliminate numerous trips to the stock room, autoclave, etc. Simply stack glassware, chemicals and equipment on the shelves and safely transport to the laboratory table or work bench. Utility carts have also proved useful mobile supports for special or heavy equipment, such as a mill that is used intermittently or in various departments.

The carts are made entirely of stainless steel with riveted joints. To protect equipment, shelves are fitted with guard rails or a combination guard rail and turned rim. Insulation under shelves deadens noise. Swivel ball-bearing casters and handle make these carts easy to maneuver. Shelves measure $17\frac{3}{4}$ by 27 inches. Over-all size, 18 by 30 by $32\frac{1}{2}$ inches. Height to top surface, $30\frac{1}{2}$ inches.

Supplied in Two Convenient Types

JL51920—Utility Cart, with center shelf, each	\$54.50
West of Rocky Mountains, each	61.50
JL51922—Same, without center shelf, each	49.50
West of Rocky Mountains, each	55.00

Cantor Tube Gives More Positive Intestinal Intubation

DIFFICULT CASES SUCCESSFULLY INTUBATED

Many of the usual difficulties encountered in intestinal intubation are readily overcome by using the Cantor Tube. Nurses and doctors who follow the carefully detailed instructions report successful intubations in difficult as well as routine cases.

A combination neoprene and natural rubber bag is attached to the Cantor Tube at its distal end. When the bag is filled with a few ounces of mercury, the free-flowing properties of the mercury and the bolus-like nature of the bag aid passage of the tube through the stomach and pylorus.

Tests prove that neoprene is far less permeable to the intestinal gases than commonly-used latex bags, as it avoids earlier hazards of a high concentration of gas in the bag due to intra-intestinal pressure when the tube is in position.

Among other features of the tube are a larger luminal diameter, allowing more efficient decompression and less possibility of plugging. There are no metal parts anywhere on the tube which might injure the mucosa. Bag and tube

are so assembled and filled that air cannot enter the bag, nor can mercury escape into the tube.

Detailed instructions, in English or Spanish, on use of the Cantor Tube are available for distribution to hospital personnel in any quantity from Clay-Adams.

You may be interested...

- For prolonged gastro-intestinal intubation, without irritation or tissue reaction, Levin-type tubes can be made readily from lengths of polyethylene tubing. It has been found particularly useful in the treatment of adults and premature and other infants, where feeding is a problem.
- Levy-Hausser Counting Chambers are recommended for determining eosinophil counts during ACTH treatments. These counts are a guide to blood level of ACTH.

CRI* Germicide for Heat-Labile Materials

Disinfection of heat-labile materials and appliances, such as plastics, catheters, and polyethylene plate and tubing, can be carried out safely in CRI Germicide. This new non-toxic, non-irritating cold germicide has a double advantage: it is effective against all common pathogens, and it is rust-inhibiting. Costly instruments, like cystoscopes, and appliances may be left in CRI Germicide with no fear of pitting or loss of cutting edge.

Descriptive literature in English and Spanish is available from Clay-Adams.

FROM CURRENT LITERATURE

Pure polyethylene plate is finding increased use in cranioplasty. Indications are that it will eventually replace other materials, metal, plastics, and bone now in use, report Drs. Eben Alexander and Peter H. Dillard in *Journal of Neurosurgery*, VII, 6, pp 492-498, 1950.

Polyethylene is readily molded by immersing in boiling water for a few seconds and then fashioning to fit the skull defect. On cooling, polyethylene retains its shape. Pure polyethylene (*i.e.*, Clay-Adams "animal-tested") causes no tissue reaction or ensuing abnormalities.

Buckstein Air Insufflator for Colonic Aerograms

In many cases small polyps and malignant tumors escape detection by means of the conventional barium enema. An aerogram, however, immediately after evacuation of the barium by the patient, will frequently disclose such pathology, as shown in the figure below.

The Buckstein Air Insufflator permits gradual entrance of air into the colon. Air is pumped from one bulb into a second bulb, and its flow into the colon controlled by a petcock. Patient distress is minimized since an even, gradual flow is more readily tolerated.

Left Buckstein Insufflator
Right Aerogram—papilloma visualized

Skeletons and Anatomical Models Help Doctor-Patient Relations

Better patient relations with the doctor often depend on the patient's understanding of his ailment and the prescribed treatment. This requires education of the patient—most effectively accomplished by visual aids. For this purpose, Clay-Adams offers, for the first

time in many years, prompt delivery on a complete line of skeletons, the well-known DURABLE pressed paper anatomical models, and charts.

Ten Thousand MEDICHROME Subjects have found their place in post-war teaching programs of many so-called "backward countries." With only inexpensive projection equipment and slides, effective teaching programs have been instituted without delay. MEDICHROMES (2 x 2" Kodachrome slides) cover practically all phases of the medical, nursing and biological sciences. Write today asking for complete listings in *your specialty*.

FEDERATION PLACEMENT SERVICE

THE FEDERATION PLACEMENT SERVICE will begin the following service to heads of departments or laboratories in universities, foundations, industry and government agencies training and/or employing biologists in the fields of the Federated Societies, supplying

- 1 Quarterly lists of available personnel
- 2 Semi-annual lists of position openings
- 3 Annual lists of available fellowships and exchange positions

This will supplant the previous monthly circulation of applicants alone

The Placement Service makes no recommendations as to either positions or candidates, serving only as an information agency. At the annual Spring Meeting of the Federation interviews between employers and candidates are arranged.

Forms for the registration of applicants, positions, fellowships and exchanges are available upon request from

NOTES ON THE THIRTY-FIFTH ANNUAL MEETING OF THE FEDERATION

Cleveland, Ohio, April 29-May 3, 1951

THE THIRTY-FIFTH ANNUAL MEETING of the Federation was held at Cleveland, Ohio, April 29-May 3. The Hotels Statler and Cleveland served as headquarters, scientific sessions were in the Cleveland Public Auditorium. Dr. Geoffrey Edsall, President of the American Association of Immunologists, was Chairman of the Executive Committee of the Federation and presided at the Joint Session held in the Public Auditorium on Monday evening.

Scientific sessions of the constituent Societies began Monday, April 30, and continued through Thursday afternoon, May 3. One hundred and twenty-six scientific sessions were held, at which 1298 papers were presented and 175 were read by title. Motion pictures were shown at a special session Tuesday evening. There was a Mixer and informal reception, arranged by the Local Committee, immediately following the Joint Session on Monday evening. Symposia were presented by the American Physiological Society, the American Society of Biological Chemists, the American Institute of Nutrition and the American Association of Immunologists. Three Societies had dinner meetings and various other groups arranged special functions such as business meetings, dinners and luncheons. The total registered attendance was 4787. Forty-nine industrial exhibits and 13 exhibits by members of the Federation were shown.

FEDERATION ACTIONS

The following actions of general interest were taken by the Executive Committee of the Federation:

1. Action on the proposed Constitution printed in the December 1950 issue of the *Proceedings* was deferred. By unanimous vote, ratified at the business meetings of the member Societies, Federation By-Laws 1, 2 and 8 were changed to provide for an 18-man Executive Committee with the Chairmanship passing in rotation among the Past-Presidents of the member Societies. A new committee will be appointed to consider further

suggestions for a Federation Constitution and By-Laws.

2. The Federation assessment for the year July 1, 1951 through June 30, 1952 was set at \$3 per member of each constituent Society.

3. Dr. M. O. Lee was reappointed Federation Secretary.

4. Plans were confirmed to hold the 1952 meeting in New York City April 14-18, and the 1953 meeting in Chicago April 6-10. The meeting will be held in Atlantic City in 1954 and on alternate years thereafter.

5. The American Physiological Society will be host Society for the 1952 meeting and will arrange the program for the Joint Session. Dr. D. B. Dill, as Past-President of the Physiology Society, will serve as Chairman of the Executive Committee beginning July 1, 1951.

6. A meeting of the Executive Committee of the Federation will be held in January 1952.

7. The subscription price of *Federation Proceedings* to non-members was raised to \$6 per year, effective with Volume 11, 1952.

MILITARY UTILIZATION OF SCIENTISTS

The Federation is interested in the proper and best utilization by the armed forces of the scientific skills of its members who are serving temporarily. It is requested that members who enter active military service by enlistment, commission or from the reserves notify either the Secretary of their Society or the Federation Secretary for purposes of record. The Federation will attempt to obtain the correction of gross misassignment, or misutilization of skills of any members who request its help.

PLACEMENT SERVICE

Beginning with the February quarterly list of applicants, the lists of the Placement Service will be supplied on a subscription basis. Information as to rates will be distributed to those receiving this service. The registration fee for applicants will be increased to \$3 annually.

CORRECTIONS AND ADDITIONS TO MARCH ISSUE

Page 34 DERN AND PULLMAN, *5th line from end of abstract* The phrase " $P = 0.1-0.02$ " should read " $P = 0.01-0.02$ "

Studies on synergism of several anti-neoplastic agents ABRAHAM GOLDIN, EZRA N GREENSPAN AND EMANUEL B SCHOENBACH *Clin Research Unit of Natl Cancer Inst, U S Public Health Service, U S Marine Hosp, and Dept of Preventive Medicine, Johns Hopkins Univ School of Medicine, Baltimore, Md*

Combinations of anti-neoplastic agents which had been shown to be effective when employed individually, were studied with respect to host survival time, inhibition of local tumor growth, and peripheral leukemic manifestations in dba mice inoculated with a transplantable acute-stem-cell leukemia (Lymphoma 1210). The combinations studied included the following agents: 5-amino-7-hydroxy-1H-v-triazolo [d] pyrimidine (guanazolo, 8-azaguanine), 4-amino-pteroylglutamic acid (aminopterin), methyl bis (B-chloroethyl) amine (HN2), alpha-peltatin, and 2,4,6-triethylenimino-s-triazine (TEM). Combined treatment with guanazolo plus aminopterin, guanazolo plus alpha-peltatin and aminopterin plus alpha-peltatin appeared to exert an additive inhibitory effect on the tumor without proportionate increase in host toxicity. Survival time was more prolonged than was observed when the drugs were employed individually. The other combinations of agents also affected the local growth and peripheral leukemic manifestations of the tumor to a greater degree, but the resultant host toxicity was increased to such extent that no prolongation of survival time was apparent.

Experimental radiographic visualization of the gallbladder J O Hoppe, J C Seed* and J W Hart,* *Sterling-Winthrop Research Institute, Rensselaer, N Y* Radiopaque substances are used as diagnostic aids for visualizing soft tissue structures. A brief outline of some of the steps involved in the search for an improved cholecystographic medium as well as myelography and urography are illustrated. See also HOPPE, J O and S ARCHER *Federation Proc* 10:310, 1951

Retraction The findings on holophosphorylase reported by Irwin Feigin, Jerome Fredrick and Abner Wolf in *Federation Proceedings*, Volume 9, page 170, 1950 and Volume 10, pages 181 and 184, 1951, are hereby withdrawn at the request of Irwin Feigin and Abner Wolf, since the results described cannot be duplicated.

JOINT SESSION OF THE FEDERATION

Cleveland, Ohio, April 30, 1951

Chairman GEOFFREY EDSALL

PHYSIOLOGICAL ADAPTATION TO COLD IN ARCTIC AND TROPIC ANIMALS

LAURENCE IRVING

From the Arctic Health Research Center, Anchorage, Alaska

DURING recent years, and with the assistance of numerous colleagues, I have been carrying on studies of adaptations to arctic cold which might be described in physiological terms. As a result of these studies, we have developed an outline of the physiological economy of heat which appears useful as a guide for further investigation. Certain physiological systems are arranged in arctic animals for the conservation of heat, thus the metabolic costs of living in low temperature are apparently held down to about the same basal level of energy expenditure as is found in warmer climates. Observation of free wild arctic animals does not indicate that they expend more time feeding than do their relatives in warmer areas. In consequence they have time for the social, mating, play and explorational activities which are equally essential in any climate for the preservation of a race.

I do not hesitate to call adaptive those devices possessed by arctic animals, and deficient in tropic forms, which obviously serve to conserve heat. Certain other physiological characters concerned with heat appear to be common to all climates, these are nonadaptive to cold and part of the common heritage of the warm-blooded condition.

We have recently measured the body temperature of arctic reindeer and dogs near the village of Barrow during a period in which the air temperature remained below -45°C for a week. We have measured the rectal temperature of porcupines in the Talkeetna Mountains at temperatures around -30°C . These animals were living freely under natural conditions. In order to obviate the effects of disturbance during observation, the measurements were confirmed upon

animals which were shot while at rest. We have gone to some trouble to ascertain that in the free condition the body temperature of arctic animals is, as reported for a few captives (1), characteristic of the warm-blooded state rather than of the climate in which they dwell. Body temperature is therefore not adapted to the conservation of heat.

In earlier studies (2) we reported that the resting metabolic rate of some arctic and tropic animals was proportional to their size, as is true among animals of temperate regions. The metabolic rates of all arctic and tropic animals examined fit closely upon the curve set by the equation

$$\text{Calories per day} = k \times \text{kg}^{\frac{1}{4}}$$

The rates thus conform to the famous statement by Benedict of the relative metabolic rates of animals varying in size from the mouse to the elephant. We have found no indication that the basal metabolic rate is adaptable to cold, although I must reserve for future study some uncertainty about small arctic birds.

The length of the arctic animal's fur is conspicuous and its protective value against cold is shown by its effective use in Eskimo clothing. We have measured the insulation afforded by the fur of some arctic and tropic animals (3). In general, the insulating effect varies with the thickness of the fur. Among arctic animals the fur thickness increases with size up to that of the arctic white fox. In larger animals, such as the caribou and polar bear, no marked increase in thickness of fur is found. What further significance there may be in this interesting relation awaits study.

Knowing the factors of temperature and metabolic heat production we can test the applica-

tion of the law of cooling, using a simple expression

$$\Delta TC = K \times I \times E$$

in which ΔTC is the largest temperature difference between the animal's body and the air which can be maintained at the basal metabolic rate, K is a constant for the units used, I is insulation and E is metabolic heat production. Plotting E against ΔTC gives lines representing $I \times E$ by their slope when all basal rates are referred to 100 per cent

Applicable data are available for 9 arctic mammals and birds, 8 tropic mammals and birds along with comparable observations from other authors upon some 20 animals of more temperate regions. A plot of these observations brings out the basic system of animal heat conservation in all climates as a function of basal rate and insulation (1)

Insulation of adult arctic animals larger than the arctic fox is sufficient to enable them to maintain normal body temperature down to -30°C , the lowest attainable in these experiments. By theoretical indications and from observation of the animals' disregard for natural temperature around -50°C , it appears that arctic animals larger than the fox need not increase basal metabolic heat production until temperatures fall lower than -50°C , and then at only a small rate of increase

Insulation is so meager among animals in the tropics that even the small diurnal and microclimatic changes often embarrass these animals with cold. But well-adjusted arctic animals do not shiver in any winter weather. In the wide range of temperature tolerable to them they seem to be in a better position with reference to the temperature of their climate than animals in the tropics

This adaptive factor, insulation, is characterized by its physiological variability, for it may be suited to air temperatures of -50°C or $+30^{\circ}\text{C}$. It may promptly be changed to permit rapid dissipation of heat through the metabolism of violent exercise. It may obviously be altered morphologically during the seasons, although we have not yet measured this very apparent process

It is also interesting to note that all three physiological functions—insulation, metabolic rate and body temperature—which are related in the application of the law of cooling as if they were single factors, are nevertheless obviously

compounded of a variety of conditions which exist discretely at any one time in the animal body. Their formulation together then expresses the organization of the animal in administering the economy of metabolic heat

We have recently made some measurements of the body skin temperature of arctic mammals and birds. At Barrow, we reported temperature of the body skin of 4 dogs in air at -3°C to be from 33°C to 37°C . In air at -19°C the temperature of one dog's skin was 30°C .

This winter we were fortunate in being at Barrow Village during a period of low winter temperature. In air temperatures around -30°C to -50°C , the rectal temperature of active or sleeping dogs was around 38°C . The surface skin temperature was around 30°C , with the immediately subcutaneous temperature a few degrees higher. Contrary to some views, these powerful arctic sled dogs are unusually stable toward those accustomed to their ways. We were able to make rectal and subcutaneous temperature measurements by inserting fine needles containing thermocouples even under the skin of the paws and nose without disturbing the animals

The subcutaneous temperature of the bare foot pads was found variously to be at from $+10^{\circ}\text{C}$ to $+20^{\circ}\text{C}$ in air temperatures ranging from -30°C to -45°C . Snow did not melt on the feet, but measurements on bare skin by surface contact are uncertain in such gradients

Conditions for surface contact measurements on the bare muzzle are better and indicated low temperature. However, subcutaneous measurements on noses 2 or 3 mm below the skin surface near the hair line at the muzzle registered only a little higher than those on the surface and were surprisingly low, indicating temperatures of 10°C to 15°C . From the muzzle toward the eyes the subcutaneous temperature rose rapidly, reaching the body level on the head just back of the eyes

With the assistance of Mr. Arnold Brower, we traveled by dog team to the location of a reindeer herd at Tapogaruik, about 70 miles south of Barrow. During the week the air temperature remained below -46°C . We were able to confirm that the temperature in the hooves and lower legs of both living and freshly shot deer remained regularly at 10°C or even lower

These observations epitomize, in our opinion, many others which we have made under less conclusive conditions upon the fleshy portions

of the exposed feet of arctic animals and birds, showing that they are often lastingly at low temperature. We have long been convinced that the skin of seals and other arctic marine mammals, and the feet of ducks and gulls must persistently remain at low temperature. We regard our measurements in the arctic only as a final demonstration of an *a priori* view that the exposed uninsulated tissues of many northern mammals and birds must for long periods exist at temperatures far below the level of the mammalian body.

That this low temperature will spare expenditure of heat is apparent, but it might be argued that as an unavoidable consequence of exposure, the condition is not in adaptation. We have usually considered that the properties of biological substances are set to operate well at normal mammalian body temperature levels. However, the cold state of some mammalian tissues as found in these studies imposes some possible difficulties in this concept. As substan-

tiation of this, we have obtained, through the aid of Dr. Norman Abrahamsen, measurements of the melting point of fat from the marrow of the hind leg of a caribou shot near the Meade River in November. In the distal metatarsal bones the fat was soft, melting at 15° C, while in the upper femur, well within the body, it was 47° C. There are other indications that the fats in tissues exposed to low temperature have low melting points (4), and thus afford the apparent advantage of preserving flexibility in the cold.

I cannot forego the suggestion that certain tissues of warm-blooded animals in the arctic must have in this and other respects a sort of chemical adaptation of their substances to suit them for operation at temperatures lower than that of the mammalian body. In accepting this view, if it is reasonable, we will considerably modify the further experimentation by which we will search for physiological adaptations enabling animals to live successfully in arctic climates.

BIOCHEMICAL MECHANISMS IN INSECT GROWTH AND METAMORPHOSIS

CARROLL M. WILLIAMS¹

From the Biological Laboratories, Harvard University, Cambridge, Massachusetts

Each of us at the outset of his or her individual life story is macroscopic and one sole cell. By that cell's multiplication and by its descendants' coherence, each of us attains final form and size. The doings of this cell-assembly are those of a being which is a unity. Yet each of its constituent cells is a life centered in itself—managing itself, feeding and breathing for itself, separately born and destined separately to die. Further, it is a life helped by and in its turn helping the whole assembly, which latter is the corporate individual.

SIR CHARLES SHERRINGTON (1)

FOLLOWING Sherrington, we can recognize the growing organism as an expanding community of cellular lives, each centering in itself and yet each presupposing the whole. The growth and differentiation of this community takes place in a coordinated manner and according to a detailed blueprint inherited from the preceding generation. Indeed, genetics tells us that each cell is equipped with such a blueprint in its nucleus. A central problem of our science is to understand how the cells, as 'servants of the genes,' execute the hereditary plan of the final organism.

The phenomena here encountered are obviously not peculiar to the higher and more pretentious organisms such as the human species. In the tiger, as in the tiger beetle, growth, differentiation, and cellular coordination present substantially the same triad of problems.

The riddle of cellular differentiation seems no less baffling today than it did to preceding generations of biologists. We can only hope that the geneticist and the experimental embryologist, approaching the problem from opposite ends, may ultimately break through to one another. Most happily, however, significant progress has been made in understanding the two other aspects of the matter, namely, the mechanisms of cellular growth and intercellular coordination. Biochemistry with its new emphasis on synthetic processes is at long last gaining access to growth phenomena at the molecular level. Likewise, the physiologist is finding cellular events to be coor-

minated and controlled by chemical agents conveyed by blood or released from nerve.

It is from these biochemical and endocrinological points of view that I propose to consider what we have learned during the past few years about the coordination of growth and the growth process itself. The studies to be considered represent the joint effort of a group of investigators, chiefly graduate students, working at the Harvard Biological Laboratories. Insects were chosen as the subject of our study since the metamorphosis which punctuates their life history gives expression to morphogenic events which in most other animals are reserved to the early stages of embryonic development.

CECROPIA SILKWORM

Consider, for example, the *Cecropia* silkworm—an insect I shall use as a text for physiological thinking about the phenomenon of metamorphosis. Postembryonic development is here partitioned into three epochs: the growing larva, the quiescent pupa, and the reproducing adult. The transition between these successive stages is called metamorphosis.

The larva is fundamentally a digestive tract equipped with caterpillar tread. From the vegetation upon which it feeds, it acquires a stock pile of fat and protein which is stored away in a special tissue called 'fat body.' In a very real sense, the accumulation of this reservoir and stock pile is the biochemical objective of larval life. Thus the pupa, which forms within the larva during the pre-pupal period, is a closed system, save for the gradual evaporation of water and the interchange of respiratory gases. Likewise the moth, which forms within the pupa during the

¹ A number of studies considered in the present communication have been supported, in part, by the Lalor Foundation, the American Cancer Society, Inc., and the Public Health Service.

period of adult development, must also be built from the assets which the caterpillar has accumulated. For though the moth possesses a normal-looking digestive tract, it cannot be used because mouth parts are lacking at its anterior end. This paradox is answered by the finding that the 'normal-looking' digestive tract is devoid of digestive enzymes and therefore incapable of functioning. (2) So, notwithstanding the fact that the larval, pupal, and adult insects are organized according to different plans, the three stages are, biochemically speaking, a reworking of the same old atoms and molecules.

ANATOMY OF METAMORPHOSIS

Metamorphosis begins at the end of larval life during the so-called prepupal period. The specialized structures of the caterpillar are at this time dismantled to make way for the equally specialized structures of the pupa. Dismantling of the one and construction of the other proceed side by side as the organism reshapes itself according to a new plan. These events are camouflaged by the old caterpillar skin which, like a loose sack, continues to cover the insect during the prepupal period. The shedding of this skin at the time of the pupal moult reveals the pupa itself.

Now the pupa is a stage of transition between larva and adult. It represents the first great stride in the metamorphosis of the species—a metamorphosis so profound that it amounts to the fabrication from the caterpillar of an essentially new organism, the adult moth.

If we look inside such a pupa, we find it filled with a great paired mass of fat body, the biochemical inheritance from the caterpillar. A more detailed search reveals the presence of a number of longitudinal structures: a dorsal heart and gonads, a ventral nervous system, and a central gut. Only in the skin of the pupa do we find any indication of the form of the future adult moth. Here the epithelium, but a cell's depth in thickness, shows a simple mapping-out of the moth's head, thorax, and abdomen. From this modest beginning within the pupa there is destined to develop the final adult insect, whose internal organization is no less complicated than that of a human being.

PUPAL DIAPAUSE

In the Cecropia silkworm as in many other insects, adult development does not proceed

promptly after the pupa is formed. To the contrary, the rapid tempo of cellular events, which during a period of seven weeks has transformed the egg into the pupa, now comes to an abrupt halt. During the months that follow, the pupa persists in a state of developmental standstill, the pupal diapause.

For the insect in nature, the period of pupal dormancy provides for the overwintering of the species. Though the pupa makes no morphological advance during this period, the months of exposure to winter's low temperature are not 'time out'. By its direct action within the pupa, low temperature promotes certain endocrinological changes which assure the termination of diapause the following spring. Such a chilled pupa, after a few days of exposure to room temperature, shows an abrupt initiation of adult development signalling the termination of diapause. The construction of the moth within the pupa then proceeds with clock-like precision so that, at a temperature of 25°C, the adult insect emerges 21 days thereafter. It has taken ten months to develop that moth from the initial egg. And of the ten months, eight were assigned to the pupal diapause.

ENDOCRINE CONTROL OF DIAPAUSE

From the biochemical point of view, the most interesting aspect of metamorphosis is the pupal diapause. Here the biochemical mechanisms underlying normal growth and differentiation are mirrored in the abrupt transitions from growth to diapause and, with the latter's termination, back to growth. Since this sequence can be controlled at the convenience of the investigator, the matter becomes accessible to experimental analysis.

In view of the synchronization of morphogenic events at the cellular level, one fact is self-evident: there must be some overall control of the genesis and the termination of diapause. And it is no surprise to find this controlling mechanism to be endocrinological in character.

This fact is perhaps best illustrated by the behavior of the male sex cells of the dormant pupa when cultured *in vitro* (3, 4). If one removes the testis from a diapausing pupa and tears it open in a few drops of the insect's blood, an enormous number of little hollow cysts are released. The walls of each cyst are formed by a simple layer of undifferentiated cells, the primary spermatocytes. At the beginning of adult development each

of these cells undergoes two divisions (meiosis), followed by rapid differentiation into the spermatozoa of the moth

When the dormant cysts of the pupal testis are placed in a simple hanging drop of the insect's blood, their behavior is remarkably conditioned by the status of the animal which donated that drop. In the blood of a diapausing pupa, the cysts show no significant development, though they survive for approximately a week (fig 1A). In contrast, if one uses a drop of blood from a pupa that has just initiated adult development, the cells undergo prompt meiosis followed by differentiation into normal spermatids (fig 1B).

The behavior of the spermatocytes in the hanging drop is therefore a kind of scale model of what goes on in the intact insect. During diapause the blood lacks a growth hormone which is necessary for the growth and differentiation of the testicular cells and of all other tissues. The secretion of this hormone in adequate titer terminates diapause and substitutes exuberant growth for developmental standstill. It seems proper to term this important growth factor the "growth and differentiation hormone" (5).

Time does not suffice to consider the role of this hormone in detail. Suffice it to say that growth at all stages in the life history seems to require its presence. It appears to be necessary for the growth and recurrent moulting of the larval insect, for the transformation of the larva into the pupa, and for the fabrication of the adult moth within the pupa. And, as we have seen, its absence following pupation results in the deficiency syndrome which we recognize as the pupal diapause.

As a growth factor of no mean proportions, the properties of this growth and differentiation hormone are of obvious interest. At long last this problem has become accessible by virtue of the assay method now provided by the tissue-culture technique. When tested in this manner, the hormone is found to behave as a protein or a smaller molecule tightly bound to a protein. It is non-dialyzable, stable when heated to 75°C for 5 minutes, but precipitated by exposure to 80°C for 5 minutes (4). It has been impossible to mimic its action by any vertebrate hormone, vitamin, or biologically active substance.

The first visualization of the growth and differentiation hormone is presented in figure 2 (6). Six components are encountered in the electrophoretic pattern of active blood obtained from post-diapausing pupae. Figure 2A shows the still-

active blood after exposure to 75°C. Figure 2B shows the inactive blood after heating to 80°C. We suspect that the small protein peak, present in A but absent in B, is attributable, in part, to the hormone itself.

In the intact insect the source of this growth and differentiation hormone has been identified. It is secreted by a pair of endocrine organs within the thorax, the 'prothoracic glands'. Curiously enough, these glands are able to secrete the hormone only under the tropic stimulation of a further hormone arising in 26 neurosecretory cells within the brain itself (7-12).

So within the insect we recognize the presence of a miniature endocrinological system—the prothoracic glands secreting the growth and differentiation hormone but only when triggered to do so by the brain hormone (fig 3). Morphogenesis in this indirect manner is brought under the control of the brain, a rational device, since the brain then becomes the meeting place of the two great systems of integration, the nervous system and the endocrine system. Though the pupal diapause of the *Cecropia* silkworm results from the absence of the growth and differentiation hormone, it is noteworthy that the primary defect occurs at the level of brain function—the failure of the pupal brain to evoke adult development by triggering the function of the prothoracic glands (9, 13). The brain regains its secretory powers when exposed to the low temperatures of winter and, thus, the insect's life history is synchronized with the seasons (fig 3).

ENZYMOLGY OF METAMORPHOSIS

But the most interesting problem is still to be considered. Hormones are merely reagents. The reactants are the target organs, in this case the various tissues of the pupal insect. Between the hormonal reagent and the tissue reactants, a reaction must occur. And there is no reason why such a reaction should not be understandable in biochemical terms.

Now the simplest approach to the problem is diagrammed in figure 3. Let us assume that a biochemical defect is present in the cells of the diapausing pupa which prevents their metabolism from coupling to morphogenesis. This view would require the growth and differentiation hormone to promote some synthetic process which repairs the biochemical defect. I now propose to consider what evidence has been obtained as to the existence and identity of this hypothetical defect in the cells of the diapausing insect.

The first useful piece of information is the insensitivity of the diapausing pupa to cyanide. Though cyanide is one of our best insecticides, killing the caterpillar or the adult moth promptly, for the pupal insect it is not even a poison. Indeed, in our surgical maneuvers on pupae, we routinely use a Ringer's solution containing 0.01 M potassium cyanide. One can implant crystals of cyanide into a diapausing pupa without any ill effects. At the pH of the insect the agent is rapidly excreted through the tracheal system in the form of HCN. But before this occurs, its only

components, the pupal heart, for example, continues to beat normally when isolated in cyanide Ringer's. In the adult moth the situation is radically different. Here we find a well-developed cytochrome system in the vast majority of the insect's tissues. Evidently a remarkable synthesis of the cytochrome system takes place during adult development.

In order to appraise the matter in quantitative terms, cytochrome *c* was extracted from post-diapausing individuals and assayed spectrophotometrically (10, 12). Only a trace was found prior

Fig 1 CYSTS OF DORMANT PUPAL spermatocytes in hanging-drop cultures. A The cysts have been cultured in inactive blood from a diapausing pupa and show no development. B The cysts have been cultured in a drop of active blood from a postdiapausing insect. The growth and differentiation hormone has caused each spermatocyte to undergo meiosis and prompt differentiation. Each cyst is thereby transformed into an elongate bundle of spermatids. Smallest division on scale equals 10 μ .

Fig 2 ELECTROPHORETIC patterns of dialyzed blood from post-diapausing pupae. A The still-active blood after heating for 5 minutes at 75°C. B Blood inactivated by 5 minutes' exposure to 80°C. The small peak, present in A and absent in B, is thought to consist in part of the growth and differentiation hormone.

obvious effect is to paralyze the intersegmental muscles of the abdomen. Attention therefore focusses on the status within the pupal insect of enzymes containing heavy metals and, more particularly, the iron-containing enzymes of the cytochrome system.

The curious insensitivity of the pupa to cyanide becomes intelligible when its tissues are studied spectroscopically. Under the Zeiss microspectroscope only the intersegmental muscles of the abdomen show the absorption bands of the three cytochromes, *b*, *c*, and *a* + *a*₃. Lacking these

to the actual initiation of adult development. The termination of diapause and the progress of adult development were found to be accompanied by a rapid and progressive synthesis of cytochrome *c*.

Recognizing the difficulty of extracting the enzyme quantitatively, the study was repeated by manometric assay of cytochrome *c* in the brei of insects at various stages of development (14-16). The results were essentially identical with those previously demonstrated by the spectrophotometric method. There can be little doubt that the synthesis of cytochrome *c* begins its

synchrony with the termination of diapause and continues in step with the progress of adult development

Cytochrome *b* and cytochrome oxidase were found to behave somewhat differently. Indeed the initiation of adult development is accompanied by a precipitous *decrease* in the activities of these enzymes. In the case of cytochrome oxidase, the initial decrease is followed by a rapid synthesis which begins on approximately the second day of development (12, 14). To the contrary, the low activity of succindehydrogenase presumably mirroring the function of cytochrome *b*, persists throughout the first half of adult development and only thereafter undergoes rapid increase (17). These changes in cytochrome *b* resemble in all respects the behavior of the two dehydrogenases we have studied, namely, malic dehydrogenase and α -glycerophosphate dehydro-

From these enzymatic studies we learn that the diapausing pupa, with the exception of its abdominal muscles, is characterized by a cyanide-stable flavoprotein functioning as terminal oxidase. At the outset of adult development this system begins to break down and is replaced by a cytochrome system containing an increasing titer of cytochrome *c* and a temporarily decreasing titer of cytochrome oxidase. Thus the termination of diapause is accompanied by profound alterations in two of the three great electron transmitters—flavoprotein and cytochrome. In the absence of the cytochrome mechanism, the flavoprotein system can apparently provide for maintenance, but not for mitotic activity or that forward progress which we recognize as growth. The coupling of growth to metabolism appears to be synchronized with the synthesis of the cytochrome mechanism.

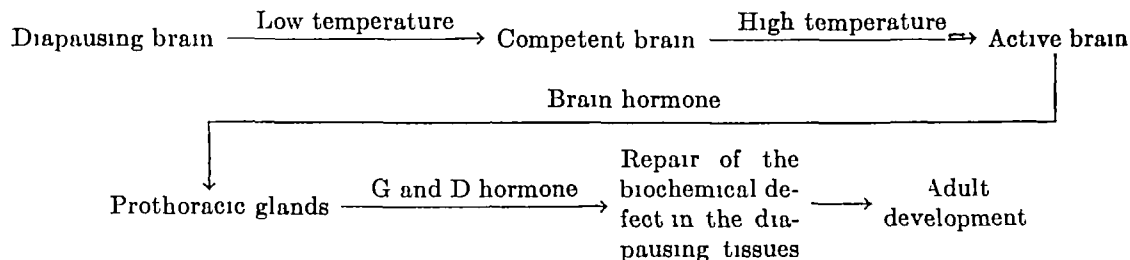

Fig 3 DIAGRAM of endocrine control of adult development by the brain and prothoracic glands. For explanation, see text.

genase. A resemblance is also evident between these results and those obtained by Agrell (18, 19).

Consequently, the activation of the growth mechanism at the outset of adult development and the sudden release of mitotic activity show a positive correlation with the behavior of cytochrome *c* and a negative correlation with the changes occurring in cytochrome *b*, cytochrome oxidase, and the two dehydrogenases that we have studied.

In the absence of the cytochrome system, the pupal insect is still able to consume oxygen apparently by the use of a flavoprotein as terminal oxidase. Biological assay of protein-bound riboflavin demonstrates a maximal titer of flavoprotein during diapause and a progressive decrease following the onset of adult development (14, 16). Since the autoxidation of flavoprotein produces hydrogen peroxide rather than water, it is noteworthy that the changes which it undergoes are paralleled by those occurring in catalase.

Our search for a biochemical defect in the diapausing insect has therefore revealed at least one such defect in terms of the absence of a functional cytochrome system. Is it possible that the cytochrome mechanism plays some special role in morphogenesis and that the absence of this system is the fundamental biochemical defect in the diapausing cells? I shall finally consider evidence that tends to answer this question in the affirmative.

If the function of the cytochrome system is prerequisite for morphogenesis, then growth should be brought to a standstill by inactivation of this enzyme system. Fortunately, in an animal such as an insect, where hemoglobin is absent and where environmental gases pass directly to the tissues through the tracheal system, it is possible to block the function of the cytochrome system by a highly specific agent, carbon monoxide. Only one difficulty is encountered: the combination of cytochrome oxidase with carbon monoxide is reversed by oxygen. The ratio between the ten-

sions of carbon monoxide and oxygen must therefore be high, in any case not less than about 20 to 1.

We have used two means to accomplish this end. In the first method the animals were placed in air-filled chambers and compressed with 3 to 10 atmospheres of carbon monoxide. In this manner the oxygen tension was held constant and the carbon monoxide tension and total pressure increased. In the second method the experiment was performed at a total pressure of one atmosphere, the animals being placed in a chamber and exposed to a mixture of 5 per cent oxygen and 95 per cent carbon monoxide. Thus the total pressure was held constant and the oxygen and carbon monoxide tensions varied.

Substantially the same results were obtained by the two methods (17, 20). Diapausing pupae were unaffected. Pupae just prior to the initiation of development remained alive but underwent no development during the experimental period of 21 days. In the case of animals that had already escaped from diapause, the carbon monoxide caused a complete or almost complete cessation of development and enforced an artificial diapause which persisted during the experimental period of 21 days. When returned to air such animals usually recovered promptly and resumed development where they had left off.

Results of this character consistently observed during the past three years, strongly suggest that the cytochrome system plays a crucial role in the metabolism of morphogenesis (21). We find this to be true, not only in the *Cecropia* silkworm, but also in the several other insects which we have examined, for example in the adult development of the blowfly *Phormia* and the parasitic wasp *Mormoniella*. Indeed, by exploiting the transparency of *Mormoniella*, it has been possible to demonstrate a partial reversibility by light of carbon monoxide's inhibition of growth (17). This result confirms a previous finding on *Drosophila* (22) and gives assurance that carbon monoxide's power to dissociate growth from maintenance results from its combination with cytochrome oxidase.

Among several hundred chemicals which we have tested, selective blockade of the growth mechanism has been accomplished by two further agents—diphtheria toxin and certain imidazole derivatives (23).

Injection of 0.1 to 1 γ of diphtheria toxin into mature caterpillars or post-diapausing pupae causes prompt cessation of development followed

by delayed death about a week thereafter. Diapausing pupae, however, survive 1000 times this dose of toxin. Its only visible effect is to render the intersegmental muscles of the abdomen flaccid and uncontractile.

These results become intelligible in terms of Pappenheimer's (24) previous studies where diphtheria toxin was found to correspond apparently to the free protein moiety of the diphtheria bacillus' cytochrome *b*. Its astonishing toxicity for the mammal is thought to result from its functional derangement of the cytochrome system.

Consequently, within the diapausing insect, the toxin finds no mechanism of action, save in the abdominal muscles, the only tissue possessing an intact cytochrome system. However, in the growing larva and developing adult, the reaction between the toxin and the cytochrome system causes a prompt cessation of growth.

It is possible to accomplish this same end by the use of imidazole and certain of its derivatives, namely, pilocarpine, dimethyl imidazole, and methyl imidazole (23). These substances are distinguished by their remarkable affinity for oxidized heme (hematin) with which they combine to form a stable hemichrome (25). Evidently, within the living insect they act as scavengers of hematin and render this important molecule unavailable for the synthesis of cytochrome. Though the pupal insect continues to live for a year or longer after the injection of pilocarpine, the onset of adult development is permanently prevented. In insects that have already terminated diapause and initiated the synthesis of the cytochrome system, pilocarpine is still capable of blocking development, though the threshold is now twenty times higher than that of the pupa. Developing animals blocked in this manner undergo delayed death several weeks following injection.

Summing up the information available at the present time, we find that the growth mechanism can be dissociated from the metabolism of maintenance by the action of several substances whose biochemical target within the living cell is the cytochrome system. As Needham (26) has prophetically remarked, "It almost looks, therefore, as if non-ferrous respiration cannot be geared to morphogenesis."

Our initial objective of understanding the biochemistry of insect growth and metamorphosis has therefore led us far afield—to a meeting place between energy and synthetic mechanism at the subcellular level. But as far as our initial and

humbler objective is concerned we feel assured that the synthesis of the cytochrome system from its hemochromogen precursors is causally related to the termination of pupal diapause. We are therefore persuaded to regard the absence of the cytochrome system as a basic biochemical defect

in the cells of the diapausing insect. Since the repair of this biochemical defect, as we have seen, is brought to pass by the 'growth and differentiation hormone,' the way seems open to an analysis of this endocrinological reaction in biochemical terms.

FATE OF I¹³¹ LABELLED BOVINE GAMMA GLOBULIN IN RABBITS*

F J DIXON, S C BUKANTZ, G J DAMMIN AND D W TALMAGE

*From the Departments of Pathology and Medicine, Washington University School of Medicine,
St Louis, Missouri*

THE TECHNIQUE of labelling and tracing protein antigens with radioactive iodine is being used increasingly in immunologic studies. Mention of a few of the more important chemical, physiological, and immunological features of this technique will indicate both its possibilities and its limitations. I¹³¹ can be added to almost any protein in traceable amounts without altering the protein immunologically. Accurate quantitation of I¹³¹ in blood, tissues, or immunologic precipitates is possible with a Geiger counter, using proper absorption and coincidence corrections. These radioactivity measurements indicate the concentration of antigen in the material tested. In addition, approximate histologic localization of the I¹³¹ antigen can be obtained with autoradiographs, in which ordinary histologic sections are mounted on special photographic emulsions and, in effect, take a picture of their own radioactivity. Autoradiographs do not, however, permit the detailed histologic localization possible with fluorescent antibody (1) or dye-labelled proteins (2, 3).

Protein antigens labelled with I¹³¹ appear to retain the I¹³¹ label *in vitro* (4) and *in vivo* (5) as long as they are immunologically active. The studies of Knox and Endicott (5), as well as our own observations, show close agreement between quantitative precipitin and radioactivity determinations of antigen.

Catabolism of I¹³¹ protein antigens liberates non-protein-bound I¹³¹, and in animals pre-

ferred ordinary iodide, this liberated I¹³¹ is rapidly eliminated, primarily in the urine with lesser amounts in breath and feces. Following injection of an I¹³¹ antigen, the radioactivity in blood and tissues can be separated into protein-bound and non-protein-bound fractions, the protein-bound activity represents residual antigen while the non-protein-bound I¹³¹ present in the blood and tissues, plus that excreted in the urine, provides a reliable index of the rate of antigen catabolism. This technique, therefore, gives an excellent quantitative measure of antigen concentration in blood and tissues and also indicates rate of antigen catabolism.

Before discussing our observations on the rabbit's handling of the antigen, I¹³¹-labelled bovine gamma globulin (I*-BGG), let us look first at the rabbit's metabolism of his own plasma globulin. Madden and Whipple (6) have shown that plasma proteins exist in dynamic equilibrium in vascular and extravascular fluids and serve to supply, in part, the nutritional needs of the body's tissues. Our findings using homologous globulin labelled with I¹³¹ (I*-RG) concurred with their's. Figure 1, which is a semilogarithmic plot of the labelled globulin content of blood against time in days, shows that within one day after intravenous injection there was a sharp drop in the I*-RG blood content to approximately one-third the amount injected. This drop represents the equilibration of I*-RG between vascular and extravascular components of the plasma protein pool and indicates twice as much globulin in extravascular as in vascular fluid. Once the equilibrium was established, the I*-RG disappeared at a constant rate with a half life of about 2 days,

representing the rate of catabolism of homologous globulin

I*-BGG injected intravenously into rabbits in doses varying from 1 to 500 mg was handled similarly to the I*-RG for the first 4 days (7). The second graph of blood content of labelled protein shows again the disappearance curve for homologous globulin. In addition, the solid line represents the amount of I*-BGG in the blood

globulin at a rate almost identical with that of homologous globulin for 4 days would further suggest that in this initial period the body utilizes the heterologous globulin similarly to its own globulin.

After the fourth day, the disappearance rate of I*-BGG from the blood increased sharply. It is most likely that this increased elimination rate is caused by the appearance of antibody which,

Figs 1 to 4

following a 75-mg injection and shows an equilibration period followed by a 3-day period of catabolism similar to that for the homologous protein. It appears that this antigenic, heterologous protein equilibrates between vascular and extravascular fluids just as does homologous protein. In so doing, the antigen, no doubt, comes into intimate contact with most or all of the body's tissues. The catabolism of heterologous

however, could not be detected by our complement-fixation technique² (8) until all antigen had

² All antibody determinations were done by the complement-fixation technique described by Kent *et al*. This method employs a dilution of antigen (1:500,000) which is optimal for the detection of minimal amounts of antibody with four 50 per cent hemolytic units of complement. The minimal amounts of antibody as detected are of the order of 10 μ g antibody nitrogen per cc of serum.

been eliminated, 7 days following injection. The first antibody to appear probably combines with antigen in extravascular or intravascular fluids and the combination is rapidly eliminated from the circulating fluids and catabolized, as will be discussed later. Since this is accomplished without measurable accumulation of antigen in any organ or tissue, it is evident that the breakdown of antigen is an extremely rapid process and/or one widespread throughout the body.

The elimination of I*-BGG from the various tissues approximately paralleled its elimination from blood, as would be expected with a dynamic equilibrium of the antigen in the body. In figure 3 the amount of radioactivity per gram of tissue or blood following an intravenous injection of 75 mg I*-BGG is plotted against time in days. The activity concentration was higher in blood than in any tissue, and disappearance rates were, in general, parallel with a slight lag in the disappearance of radioactivity from the tissues after the fourth day. All radioactivity levels were insignificant after the seventh day, with no tissue showing measurable retention of antigen. Complement-fixation tests for antigen in the tissues after the seventh day were also negative.

Detectable circulating antibody appeared on the seventh day after virtually all antigen had disappeared. This is in keeping with the findings of Hawn and Janeway, who found disappearance of BGG and appearance of antibody between one and two weeks following injection of 2 gm of antigen (9). Following injection of 75 mg of I*-BGG, the peak antibody level occurred on the tenth day and all detectable circulating antibody disappeared within approximately 20 days after antigen injection. It is apparent that the first antibody is produced in the presence of antigen, but that the major part of antibody production goes on in the complete absence of antigen.

We found considerable support for the view that the increased antigen disappearance rate seen after 4 days in I*-BGG injected control rabbits is caused by appearance of antibody. Figure 4 compares blood antigen levels in 5 experimental groups of rabbits, each with a different immune response. Actively sensitized rabbits with detectable circulating antibody present at the time of injection of antigen showed rapid disappearance of antigen immediately, previously sensitized animals without detectable circulating antibody showed a rapid antigen disappearance beginning 2 days after injection, in keeping with an accelerated, anamnestic response, animals receiving 200 r whole-body γ -radiation showed

delay in and decrease of rapid antigen elimination, corresponding to the inhibition of the immune response resulting from the radiation, animals receiving 500 r γ -radiation showed neither rapid antigen elimination nor any immune response. The appearance of detectable serum antibody in these 5 groups of rabbits always followed immediately upon the rapid disappearance of antigen, as seen in figure 5. Here the 5 antigen disappearance curves are given in temporal relation to the appearance of complement-fixing antibody, indicated by the black bars. In the first 4 instances, rapid antigen disappearance was closely followed by appearance of detectable antibody, while after 500 r neither rapid antigen elimination nor detectable antibody was seen.

Further support for the relationship of antibody to rapid elimination of antigen was found after injection of passive antibody into rabbits

Fig 5

with circulating I*-BGG. In figure 6 the I*-BGG concentration in blood is plotted against an expanded time scale. The injection of passive antibody, 100 mg on second day and 40 mg on third day, caused a prompt drop in blood antigen content. The rise in blood antigen level shortly after the first injection represents the re-establishment of equilibrium of antigen between the depleted vascular fluid and the antigen-containing extravascular fluid.

On the basis of these interrelationships between antigen disappearance rate (ADR) and appearance of antibody, we have used the mathematical expression of ADR as an index of immune response (10). This measure is extremely sensitive and will reveal an immune response which may produce only enough antibody to combine with the antigen present, and not enough to cause a detectable excess in the serum. Such weak antibody responses may occur after moderate

doses of x-ray or following extremely small doses of antigen and result in rapid antigen elimination without detectable antibody. Later demonstration of a specific anamnestic response indicates that such animals have made a previous immune response to the given antigen.

removal of antigen from the blood. In investigating antigen catabolism, we attempted to find whether the increased rate of catabolism in sensitized animals could be accounted for alone by presence of antibody, and therefore, presumably by increased phagocytosis or whether there was,

Figs 6 (left) and 7 (right)

Fig 8

The mechanism of rapid elimination of the antigen-antibody combination from the blood and the associated rapid antigen catabolism are not completely understood. It is most likely that antigen-antibody complexes would be taken up by phagocytic cells, thus accounting for the rapid

also, a cellular enzymatic adaptation associated with the process of sensitization, which facilitated more rapid antigen catabolism (11). To do this, we compared the rates of I*-BGG catabolism in actively sensitized rabbits and in control rabbits given 95 mg of passive antibody, an amount calculated to be approximately equal to the amount in those actively sensitized. Figure 7 shows the rates of I*-BGG catabolism, as measured by non-protein bound I¹³¹ in urine, blood, and tissues in actively sensitized, passively sensitized, and control rabbits for the first 48 hours after intravenous injection. The rates of antigen catabolism for actively and passively sensitized rabbits were almost identical. The antigen disappearance rates in actively and passively sensitized groups were also similar. It appears, therefore, that both the increased rate of disappearance of I*-BGG from the blood and the rapid catabolism found in sensitized animals can be accounted for by the presence of antibody alone. Whether the sensitized animal makes any physiologic or enzymatic adaptation to an antigen such as I*-BGG other than the production of specific antibody cannot be definitely stated at this time. However, there is nothing that happens in the immune catabolism of I*-BGG that cannot be duplicated in a control animal by addition of passive antibody.

These findings agree with the antigen tracer study of human globulin using the fluorescent antibody technique (1). There is, however, a marked discrepancy between our findings and those obtained by workers using BGG or similar proteins labelled with various azo dyes (3). The azo dye-labelled proteins were found concentrated and retained for long periods of time in the reticulo-endothelial system. In an effort to explain these differences, we attached to I*-BGG by azo conjugation one of two compounds, R salt (12, 13) or para-aminobenzoic acid, and traced these doubly labelled antigens by both color and radioactivity. Using these antigens, we found an uptake and retention of antigen by the reticulo-endothelial system, just as described by those using the various azo dye-labelled proteins. Figure 8 indicates azo-I*-BGG concentration in blood and tissues following intravenous injection of 75 mg of the antigen. The blood level fell rapidly while tissue concentrations, especially in those tissues rich in reticulo-endothelial cells, dropped very slowly. The tissue retention of azo-I*-BGG is in marked contrast to the findings

with I*-BGG where no tissue antigen retention occurred (fig. 3). Thus, it appears that azo labelling markedly changes the *in vivo* behavior of protein antigens such as BGG.

SUMMARY

Tracing of the antigen I*-BGG in rabbits indicates that the antigen is handled much like the animal's own globulin until antibodies to it are formed. Before the appearance of antibodies, the antigen exists in equilibrium between vascular and extravascular fluids, has free access to the tissues of the body, and is neither concentrated nor retained by any tissue or organ. With the appearance of antibody, the antigen is rapidly removed from blood and extravascular fluids, probably by phagocytic cells and is rapidly catabolized. There does not appear to be any cellular enzymatic adaptation necessary in the sensitized, rapid catabolism of antigen. Antibody production, although initiated in the presence of antigen, is carried on long after all antigen has disappeared.

FLUORESCENT ANTIBODIES AS HISTOCHEMICAL TOOLS¹

ALBERT H COONS

*From the Department of Bacteriology and Immunology, Harvard Medical School,
Boston, Massachusetts*

THE ANTIBODY molecule can be conjugated with fluorescent compounds without apparent loss of specificity (1-3). This fact makes it possible to employ the precipitin reaction as a method for the histochemical detection of small quantities of material in tissue cells. The only basic requirement for success is that the material sought be sufficiently antigenic so that the requisite anti-serum can be produced.

Purified antisera were chemically conjugated with fluorescein isocyanate to produce a brilliantly fluorescent protein solution in which the antibody molecules as well as the other protein molecules are fluorescent. When such a fluorescent antibody solution is allowed to react with organisms or tissue cells containing homologous antigen, some of the antibody is precipitated over those areas where the antigen is located. The excess of the fluorescent solution can be washed away and the deposited antibody visualized under the fluorescence microscope. This reaction has so far been successfully employed to trace the fate of injected bacterial polysaccharides and foreign animal proteins after injection into mice, and to localize viral and rickettsial antigens in infected cells. In the brief time available, I will summarize the successes which we have so far had in the use of this method, list the failures and point out some of the difficulties.

When foreign substances such as bacterial polysaccharides (4) or animal proteins (5) are injected intravenously into mice, they rapidly begin to leave the blood stream and make their appearance in the connective tissue throughout the animal. They are also found in high concentration in all the phagocytic cells in the body. They can also be found in a low but distinct concentration in lymphocytes in the nodules of the spleen and lymph nodes. In general, the epithelial cells of the animal are well protected against the entrance of these antigenic materials but they all made an appearance in the hepatic cells and in

the endothelium of the renal tubules. There are minor differences in their distribution which there is no time to describe.

The most striking difference among the antigens so far studied is their rate of disappearance. Crystalline egg albumin (dose 10 mg) disappeared within a few hours. Crystalline bovine serum albumin persisted for about 2 days. Human plasma gamma globulin (dose 4 mg) persisted for a week. It is apparent that the rate of disappearance is inversely proportional in a rough way to the molecular size of the antigen. In great contrast to this rather rapid disappearance of protein antigens, the capsular polysaccharides of pneumococcus type II, pneumococcus type III, and Friedländer bacillus type B, injected in comparable doses, persisted for weeks to months. In the case of all six of these antigens, the connective tissue and the phagocytic cells of the reticulo-endothelial system contained antigen after it had disappeared from other locations.

An unexpected finding was that the protein antigens, or fragments of them, could regularly be found in the nuclei of all the cells into which they penetrated. This confirms the data of Crampton and Haurowitz, who found radioactivity in the nuclear fractions of liver homogenates after the injection of proteins labelled with I¹³¹ (6).

The method is not only useful in tracing injected foreign proteins or polysaccharides, its utility has already been demonstrated in the study of cells infected with rickettsiae and with viruses (7). For example, the cells of the monkey parotid infected with mumps virus can be readily visualized by use of labelled antibody against the mumps virus. Similarly, the rickettsiae of epidemic typhus and Rocky Mountain spotted fever have been found in infected cells in the liver and spleen of the cotton rat and in smears of the gastrointestinal tract of individual infected lice. An extensive study is now being carried out by Dr. Barbara Watson of the progress of mumps infection in the embryonated hen's egg. Two other viruses with which preliminary experiments have been successful are

¹ Aided by grants from the Life Insurance Medical Research Fund, the Helen Hay Whitney Foundation and the Eugene Higgins Trust.

influenza A virus in the infected mouse lung and in the infected hen's egg embryo, and the virus of canine hepatitis in the organs of infected dogs. Work with the hepatitis virus is being carried out in collaboration with Dr D L Coffin.

Attempts to perform the same sort of experiments with neurotropic viruses have so far failed. Although it was possible to demonstrate mumps virus in the brain of a monkey with experimental parotitis but without neurological symptoms (8), similar attempts with the Columbia strain of SK virus and Theiler's virus GDVII have been unsuccessful. Attempts to find the Lansing strain of poliomyelitis virus in infected monkey cord and brain and in tissue cultures from human skin and brain have so far failed (9).

The major pitfall in the application of this method is the very regular appearance of what we have hitherto called 'non-specific staining' (3). It is already becoming clear that much of this non-specific staining is the result of so-called natural antibody, and due to the possession of

common antigens by animal tissues of different species and bacteria with which the serum donors are frequently infected. So far in our studies, we have avoided this non-specific staining by absorbing our conjugated antisera with normal tissue from animals whose tissues it was proposed to study. But it is probable that this method is only successful when the normal tissue used for absorption contains appreciable amounts of the antigen belonging to the interfering antigen-antibody system. Much remains still to be worked out with regard to such cross reactions.

Despite this difficulty, the use of fluorescein-labelled antibody as a specific histochemical reagent has already proved to be a useful tool in the localization of antigenic materials in tissue cells. It has the disadvantage inherent in other histochemical methods in that it is difficult to quantitate, particularly so because the amount of light coming from any given cell is very small. Its advantage lies in its apparent high sensitivity, and in its specificity.

IMMUNOCHEMICAL STUDIES WITH LABELLED ANTIGENS¹

FELIX HAUROWITZ, CHARLES F CRAMPTON² AND RAYMOND SOWINSKI

From the Department of Chemistry, Indiana University, Bloomington, Indiana

PREVIOUS experiments with arsanil-azo-proteins had demonstrated that most of the antigen injected into rabbits disappears rapidly from the blood and passes into liver, spleen, bone marrow and lung (1). Similar results are obtained with iodo-ovalbumin tagged with I^{131} (2). Table 1 shows the approximate activity of various organs at different times after the injection of iodinated ovalbumin.

It is apparent from the figures recorded in table 1 that the antigen content of the organs decreases rapidly during the first hours after injection of the antigen, but that the decrease thereafter is very slow. At the end of 29 days the liver still contains 0.018 per cent of the injected activity. If this were present as unchanged iodo-ovalbumin, it would correspond to 15.5 μ g, or 2×10^{14} molecules of iodo-ovalbumin in 62 gm of liver. Since the volume of a liver cell is about 10^{-9} to 10^{-8} ml, each cell would contain approximately 10,000 antigen molecules at the end of the 29th day. Results similar to those recorded in table 1 were obtained when the amount of iodo-ovalbumin injected was reduced to 9 to 11 mg or when the iodo-ovalbumin was replaced by iodinated beef serum globulin.

In a series of experiments we injected in rabbits 2 to 5 doses of iodo-ovalbumin in intervals of 3 days. Only the last of these injections was labelled by I^{131} . The rabbits were killed 24 hours after the last injection. The distribution of the activity in the organs and in the liver fractions was the same as that which followed a single injection of I^{131} -iodo-ovalbumin.

The most interesting result of our experiments is the finding that the injected antigen is rapidly incorporated into the small granules (microsomes) and that it appears shortly thereafter in the large granules (mitochondria) where it remains for long periods of time. The separation of the granules from nuclei and from the supernatant

solution (table 1) was achieved by fractional centrifugation (2, 3). The yields of nuclei, mitochondria and microsomes were about 20 per cent of the total liver homogenate for each of these fractions, while the supernatant solution formed 40 per cent of the homogenate. All four fractions were precipitated by trichloroacetic acid and the precipitated proteins washed with acetone and ethanol. Table 1 shows the relative activities of the washed proteins of the subcellular fractions. When radio-iodinated ovalbumin was added to a normal rabbit liver homogenate under the conditions used in our procedure, only traces were adsorbed to the granules, while the bulk was found in the supernatant solution. This proves that incorporation of the antigen into the granules occurs *in vivo* and not during the fractionation. The finding of the intravenously injected antigen in cellular granules indicates that it passes rapidly through the membranes of the liver cells. Since the molecules of ovalbumin and beef serum globulin are macromolecules which are not able to pass through semipermeable membranes, we have to assume that their incorporation into the liver cells occurs by some process akin to phagocytosis.

The initial high activity of the microsomes and the subsequent appearance of most of the antigen in the mitochondria suggest that the antigen is at first adsorbed to the large surface of the small granules and that it later passes into the larger granules. Another possibility to be considered is the incorporation of the microsomes with their load of antigen into the large granules.

The persistence of the antigen in the large granules is particularly interesting because the mitochondria have been considered as self-reproducing units, i.e. as sites of protein synthesis (4). Possibly they are also the sites of antibody synthesis. This is in accordance with our view that antibody synthesis is essentially protein synthesis modified by the presence of antigen (5).

The distinct activity of the nuclei (table 1) is in agreement with recent findings of Coons and his co-workers (6). It is not clear from our experiments whether the presence of antigen in the nuclei is significant, and whether the nuclei are to be considered as antibody producing sites. The fact that immunity is never transmitted to de-

antigens. The precipitates were washed with small amounts of 0.9 per cent saline solution, then suspended in large volumes (35 ml) of saline solution for the determination of their solubility at different temperatures. After centrifugation it was found that the supernatant solution contained mainly antibody, while only traces of antigen were dissolved. Evidently, the precipitated antigen-antibody complex dissociates according

to the equation $GB_n \rightarrow GB_{n-1} + B$, where G = antigen and B = antibody. The dissociation constants found were of the order $K = 10^{-6}$ to 10^{-7} . The thermodynamical constants for combination of antigen and antibody, calculated from the values of $1/K$ at two temperatures, are recorded in table 2.

ANTIBODY FORMATION IN SURVIVING TISSUES¹

HELEN M RANNEY² AND IRVING M LONDON³

From the Department of Medicine, Columbia University College of Physicians and Surgeons, New York City

AN ATTEMPT has been made to develop a technique for determining the capacity of various tissues for synthesizing antibodies *in vitro*. This technique is designed to avoid the difficulty of determining whether antibody present in a tissue has been synthesized by that tissue or whether it has been transported to the tissue from its origin at another site.

By immunizing animals and sacrificing them at a time when their serum antibody titer is high and, presumably, when antibody is being synthesized actively, it is possible to obtain surviving tissues which are still capable of forming antibody. Incubation of a tissue, which is synthesizing antibody, with an isotopically labeled amino acid permits the utilization of the amino acid for the synthesis of new antibody protein. The capacity of a tissue for forming antibody may be indicated therefore by the presence of isotope in the antibody which is obtained by precipitation with its specific antigen.

METHOD

Young adult rabbits were injected intravenously with a suspension of formalin-killed type VIII pneumococci. Approximately 4 billion organisms were injected 3 or 4 times per week, and the animals were killed by exsanguination after a minimum of 6 weeks of such immunization. Tissues were removed and slices of 0.5-mm thickness were prepared. Approximately 10 to 15 gm of wet tissue (less in the case of spleen control) were placed in 50 cc of medium of the following composition (mm/l): Na, 142.5; K, 10; Ca, 2.5; Cl, 117.5; HCO₃, 40. About 7000 u of penicillin and 10 mg of C¹⁴ carboxyl-labeled glycine (CH₂NH₂C¹⁴OOH) were added to each flask. A stream of 95 per cent O₂ and 5 per cent CO₂ was

passed through the mixtures for 1 to 3 minutes, the flasks were then stoppered, and the preparations were incubated with agitation for 4 hours at 37° C. After incubation, the medium was separated from the tissue slices by centrifugation at high speed. The clear medium was concentrated 5- to 10-fold by negative pressure dialysis.

TABLE 1 C¹⁴ ACTIVITY OF PNEUMOCOCCUS VIII SPECIFIC PRECIPITATE

¹ C¹⁴ activity of the glycine is 1.25×10^5 counts per minute per standard dish of glycine of infinite thickness.

² Expressed as C¹⁴ activity per standard dish of specific precipitate of infinite thickness.

³ Tissues from a non-immunized animal with pneumococcus VIII antiserum added to the medium.

⁴ This value is approximate because of the correction of the actual counts (126) to counts at infinite thickness.

against buffered saline. Antibody in the medium was precipitated by the addition of an appropriate amount of pneumococcus type VIII polysaccharide. The specific precipitate was washed with cold saline three or four times and determinations of the radioactivity of the specific precipitate were carried out with a Q-gas counter. All samples were counted for a minimum of 30 min-

³ Welch Fellow in Internal Medicine, National Research Council.

utes, the radioactivity is expressed as counts per minute above background

The possibility that the radioactivity of the specific precipitate might be due to adsorption or co-precipitation of radioactive glycine or of any of its derivatives was considered. To some extent, dialysis reduced the possibility of adsorption, but to test the second possibility the following control experiment was done. Tissues from a normal non-immunized rabbit were removed and prepared in the same manner as in the previous experiment, in addition, however, serum from a rabbit which had been immunized to pneumococcus type VIII was added to the medium before incubation. The preparations were incubated, centrifuged, dialyzed, and the antibody precipitated with type VIII polysaccharide.

RESULTS

Results of these experiments are presented in table 1. Work is now in progress to confirm and to extend these preliminary findings.

The results indicate that the spleen and liver are capable of synthesizing antibody *in vitro*. Synthesis of antibody by splenic tissue has been

described by Parker (1), Fagraeus (2), and Roberts and White (3). Thus far we have been unable to demonstrate such synthesis in kidney tissue. The absence of significant radioactivity in the control indicates that non-specific adsorption or co-precipitation of isotopically labeled products does not account for the isotope activity observed in the specific precipitates of the experimental preparations. However, control preparations differ from the experimental preparations in this respect: in the latter some antibody is presumably intracellular and may be exposed to conditions different from those of the control preparations in which the added antibody may remain extracellular. Whether this consideration is significant cannot be determined at the present time.

DISCUSSION

These findings indicate that this technique affords a means of demonstrating the ability of tissues to form antibodies *in vitro*. By studying the ability of individual tissues and of smaller structural units to synthesize antibody, it may be possible to delineate more clearly the sites of antibody formation.

BEHAVIOR AND PERSISTENCE OF AZOPROTEIN TRACER ANTIGENS IN MICE¹

PHILIP D. McMASTER AND HEINZ KRUSE

From the Laboratories of The Rockefeller Institute for Medical Research, New York City

TO DETERMINE the sites from which the initial stimuli to antibody formation arise the fate of certain tracer antigens is under study. A recent paper (1) describes the preparation of some deeply blue, antigenic azoproteins, and the methods for ridding these preparations of unlinked or free dye. Following intravenous injections of these substances into mice some sort of blue material appears in various tissues and remains in them for weeks. However, the visible presence of color in tissues, like the demonstration of radioactivity following injections of radioactive tracer antigens, is no proof that intact antigen is localized in the cells. The dye may be split off rapidly while the dye protein is still circulating in the blood, so that free dye enters the cells, or, the dye may be split off from the protein after it enters the cells, and there be retained. Further, the protein portion of the azoprotein may be broken down sufficiently to lose its antigenicity, either while in the blood or soon after being taken up by the tissues.

To eliminate the first of these possibilities an extremely diffusible dye, echt-saure-blau, has been diazotized and coupled to either bovine γ -globulin (1) or to human albumin.

This dye is not degraded in the bodies of mice injected with it, instead it is so diffusible that it is rapidly eliminated from the body in 2 or 3 hours without being stored intracellularly as granules, or in vacuoles. The dye does not, by itself, form combinations with proteins. Clearly, if such a dye, coupled to a protein and injected into mice, should become split off from its protein while in the blood stream, no blue matter would appear in the cells, if split off after its

entrance into the cells, it would be rapidly eliminated from the body.

By contrast, injections of the two azoproteins, formed from this dye, unlike injections of the dye itself lead to the progressive accumulation and storage of blue granules in many organs, especially in the Kupffer cells of the liver, reticulo-endothelial cells throughout the body, and in the kidney tubules.² Consequently some sort of linked dye protein, not necessarily intact antigen, is taken up and stored. Is this material the original antigen?

STORED BLUE MATERIAL IS RETAINED ANTIGEN

Complement-fixation tests readily answered this question when carried out upon liver emulsions and blood from mice injected intravenously with the azoglobulin. Soon after the injections the deeply colored blood yielded strong reactions for antigen, the lightly colored liver tissue contained some too, but in smaller amounts, a finding that might be attributed to liver blood. However, as time passed, both color and antigen titer decreased in the blood and increased in the liver, until, in two or three days the organ held far more of both than the blood (1). The blue matter accumulating in the liver seemed to be active antigen. After a fortnight only faint traces of antigen remained in the blood, but, by contrast, the blue material, whether antigen or not, was retained much longer in the livers and mesenteric lymph nodes, indeed all the intracellular colored matter did not disappear from these organs for 85 to 120 days.

The finding suggested that antigens may persist in very small amounts, within certain cells, longer than is generally supposed, thereby stimulating prolonged antibody formation. To investigate the matter it seemed wise to study the

¹ The present note summarizes briefly some findings come upon in this laboratory during the course of work carried out with certain azoprotein tracer antigens. Since some of the work has already been published and the remainder is in the process of publication *in extenso* elsewhere, descriptions of the physiological reactions here mentioned and the presentation of data will be omitted.

² Very recent work has shown species differences in the distribution of these azoproteins. In rabbits, for example, the kidney tubules take up far more of the blue material than the livers or mesenteric nodes, although both of the latter contain much. This is the reverse of the state of affairs in the mouse.

persistence of a natural antigen, preferably the protein from which the artificial tracer was derived, because, should the natural antigen be destroyed rapidly in the body, the fate of the artificial tracer would be of little interest. Accordingly an attempt was made to determine the full span of persistence of even the faintest traces of bovine γ -globulin detectable in the blood and certain organs of mice, intravenously injected with it. Since it seemed most unlikely that the minute amounts of antigen to be detected could be successfully extracted from organs for complement-fixation tests, resort was had to a more delicate method for the pursuit of the problem.

EXTREMELY SENSITIVE TEST FOR DETECTION OF TRACES OF ANTIGEN WITHIN TISSUES AND BODY FLUIDS

An earlier paper (2) has described a technique by which extraordinary spasms and other specific vascular reactions in the blood vessels of the ears of anaphylactically sensitive mice are rendered visible under the microscope when the animals are challenged with an intravenous, shocking dose of antigen. These reactions occur even in mice too weakly sensitive to show any of the other signs of anaphylaxis. It now appears that similar ear vascular reactions, hereafter termed EVR, occur in mice injected with various antigens and challenged later with appropriate antisera (reversed passive anaphylaxis). The EVR are so sensitive that one can inject as little as 0.5 to 0.1 μ g of bovine γ -globulin, as antigen, into the peritoneal cavities of normal mice of the Rockefeller Institute strain³ and detect the absorption of some of it by a subsequent injection of very strong rabbit anti-bovine γ -globulin serum. A description of these reactions and their differentiation from certain physiological reactions which occur from time to time in the ears of intravenously injected, normal mice will be presented fully elsewhere (3), in a paper now in press, since the matter is a complicated one, and it cannot be adequately presented in a brief summary.

The extreme sensitivity of the EVR made it seem likely that mice could be used to advantage, as test animals, to detect the presence of truly minute traces of antigen persisting in the tissues

or body fluids of animals previously injected with it.

TESTS FOR PRESENCE OF ANTIGEN PERSISTING IN BLOOD OR TISSUES

Normal mice were injected intravenously with 5 mg of bovine γ -globulin (0.1 ml of a 5% solution) per 30 gm of body weight. At various intervals samples of blood and ground liver, or mesenteric nodes, from these animals (donors) were injected intraperitoneally into normal mice (recipients). Two days later, before antibody formation could take place, the recipients were intravenously injected with strong, rabbit anti-bovine γ -globulin serum. The occurrence of the specific type of EVR indicated the absorption, from the peritoneum, of antigen present in the materials transferred from the donor mice. Suitable controls were employed at all times.

PERSISTENCE OF ANTIGEN

In two series of experiments recipient mice showed specific EVR after transfer of blood from donors injected with the antigen 56 days previously. All reactions after longer periods were negative. The transfer of liver tissue, up to and including 101 days after injecting the donors with antigen, sensitized the recipients sufficiently to yield positive, specific EVR upon the injection of the antiserum. There was therefore a striking similarity in the period of persistence of the bovine γ -globulin, as antigen, in the livers of these donors (101 days) and that of the blue material, whether antigenic or not, in the livers of the other mice injected with the azoglobulin (85-120 days), as mentioned above. The finding called for a direct experiment to find out: Does the transfer of tissues from donor mice, injected with an azoglobulin, to normal recipients lead to the production of positive EVR as long as the transferred tissues show the visible presence of colored material of some sort in them? If so, it is most likely that the colored material is still the antigen.

AN AZOPROTEIN INJECTED INTO MICE SEEMS TO RETAIN ITS ANTIGENICITY AS LONG AS COLOR REMAINS VISIBLE IN TISSUES

A direct test was accordingly made. Since the 101-day period, over which positive EVR had been obtained by the transfer of liver tissue from mice injected with plain bovine γ -globulin, was so much like the 85- to 120-day persistence of color in the livers of other mice injected with

³ Different strains of mice have now been found to vary enormously in their sensitivity to reversed passive anaphylaxis. The strain used for this work is especially sensitive.

the azoglobulin, presumptive evidence seemed to be already at hand to indicate that the colored matter was still antigenic, at least as far as the azoglobulin was concerned. It seemed wise therefore to employ a different protein for the direct test, and, by so doing, to answer not only the question asked above but also two other related questions. Does an azoprotein persist, as an antigen, for the same length of time as the protein from which it is derived, and, do different proteins persist, as antigens, for unequal periods of time?

To answer these questions, a new azoprotein, prepared by coupling to human albumin the same dye that had previously been linked to bovine γ -globulin, was injected into scores of mice, as donors. At weekly intervals thereafter the presence of antigen, persisting in the blood and certain tissues in the donors, was sought by the detection tests mentioned above. As time passed, the blue material, stored in the tissues of these mice injected with the azoalbumin, disappeared far more rapidly than had the colored matter after like injections of the azoglobulin. At the 23rd day the recipients, which got transferred blood from these donors, no longer showed positive, specific EVR. At the 36th day transfer tests made with ground liver tissue, which contained only faint traces of blue material, yielded very weak, positive EVR in the recipients. The transfer of ground mesenteric nodes, which contained more persisting blue material than the livers, gave somewhat stronger detection tests (EVR) for antigen in other recipients.

Highly significant were two series of tests performed 42 and 43 days after injecting the azoalbumin into the donor mice. The livers of these animals showed no remaining blue when examined grossly, or when magnified at low powers (10 or 20 times), under a dissecting microscope. By contrast, the mesenteric lymph nodes held faint traces of blue. The recipients that got transferred liver tissue from these donors yielded negative EVR, whereas transfer of the faintly colored nodal tissue gave positive EVR. Clearly, as long as the blue material remained visible in the tissues, the detection tests for antigen remained positive.

PLAIN ALBUMIN AND DYE-AZOALBUMIN YIELD POSITIVE DETECTION TESTS FOR SIMILAR PERIODS

Scores of other donor mice were intravenously injected with plain human albumin, instead of

the azoalbumin, and transfer tests from these donors were carried out in the same manner. The EVR in the recipient mice became negative at the same time intervals as in the experiments with donor mice injected with the coupled azoalbumin, that is to say, the protein and the azoprotein derived from it, yielded positive detection tests for approximately the same length of time.

It is to be stressed that control tests, too complex to describe here, showed that the appearance of the EVR in all this work could not be attributed to traces of antigen in the antisera reacting with antibody transferred to the recipients from the donors.

WIDELY DIFFERENT PROTEINS YIELD ANTIGEN DETECTION TESTS FOR UNEQUAL PERIODS

The experiment just described answered the last of the questions posed above. Both the plain human albumin and the coupled dye-azoalbumin yielded positive detection tests on the 42nd day, after injecting the donors, but not thereafter, while the bovine γ -globulin yielded positive EVR for 101 days.

BEHAVIOR OF COLORED RESIDUES INDICATES AN UNCHANGED STRUCTURE

It is of much interest that, following the injection of plain globulin into donor mice, the detection tests for that antigen in their tissues remained positive two and one-half times as long as tests for the detection of plain albumin in the tissues of donors similarly injected with that protein. In complete accordance with this, the persistence of colored matter in the livers of mice injected with the azoglobulin and the azoalbumin, respectively, differed in the same manner. Yet the same dye was coupled to both proteins.

Had the presence of color in these tissues, long after injection, been due to dye, split off from the protein to which it had originally been coupled, and either free in the cells or bound to cellular proteins, then its persistence should have been the same in all the tests. But this was not the case. In mice injected with azoglobulin color persisted in the liver for 85 to 120 days, in the animals injected with azoalbumin color could be found in that organ for less than 42 days, and for only a few more days in the mesenteric lymph nodes. These differences are similar to the periods during which positive detection tests can be elicited after injecting the respective azo-

proteins. From all this it would seem to follow that the color behaved as though still coupled to its respective protein.

COMMENT

Since the blue tracer antigens seem to retain their antigenicity as long as blue color can be seen in the tissues they should serve not only to indicate the sites from which the initial stimuli to antibody formation must emanate, when tissues are examined a few days after injecting the animals, but they should show the whereabouts of antigen during prolonged antibody formation.

Little has been said of the distribution of these azoantigens, because a previous paper has fully described the state of affairs during the first few days after injection (1) when the blue material, taken up by the cells, has been definitely shown to be still antigenic. It has seemed best to delay an exhaustive study of the later distribution of

the blue matter seen in the cells, long after injecting mice with the azoproteins, until the work here described could indicate with more certainty whether or not the blue material is still the antigen itself, and until more could be learned about the span of persistence of some natural antigens. Such a study will be undertaken shortly.

In conclusion it is necessary to note only that the presence of intravenously injected azoprotein antigens within certain cells of the reticulo-endothelial system, long after detectible amounts have disappeared from the blood, is highly significant for hypotheses of antibody formation, for among the various reticular cells in lymph nodes and elsewhere, that take up and store these colored antigens, are some of those that may give rise to plasma cells, lymphocytes, and other cells now suspected of carrying antibody. What happens between the storage of antigen by these reticular cells and the appearance of antibody in their daughter cells is yet to be learned.

RADIOLABELLED ANTITISSUE ANTIBODIES

DAVID PRESSMAN

From the Sloan-Kettering Institute for Cancer Research, New York City

THERE have been many studies made in the field of antitissue antibodies especially in connection with certain diseases which appear to have an etiology of autoimmunization in which the mechanism of the disease process is a production by the individual of antibodies against his own tissue and a subsequent reaction of these antibodies with the tissues. Some diseases which appear to be of this category are glomerulonephritis, multiple sclerosis, rheumatic heart disease, certain anemias, periarteritis nodosa, lupus erythematosus etc. Also many attempts have been made since the turn of the century to use antisera prepared against malignant tissue, therapeutically, in the treatment of cancer. It seems reasonable that if an antibody which can produce a physiological effect is present in an antiserum it must first interact with that tissue in order to produce such an effect. Thus, progress would be made if it could be demonstrated that there are antibodies in antitissue sera which actually go to the tissue in question. Further, it is not impossible that, if antibodies can be found which go specifically to a tumor tissue, they can be made to carry physiologically active amounts of radioactivity to the tissue.

We have been able to trace the *in vivo* localization of the injected anti-kidney and anti-lung antibodies by labeling them with radioactive iodine (1, 2) or radioactive sulfur (3) and following the localization of the radioactivity. The radioactive labels can be easily attached to antibody molecules without destroying antibody activity (1, 3, 4) and the antibody can be followed very simply by following the attached radioactivity by a counting or radioautographic technique.

Actually, the fraction of the total protein in a serum which is localizing antitissue antibody is very small. Only a small fraction of the total radioactivity in a labelled serum is attached to localizing antibody since the label is distributed over all of the proteins present. Therefore suitable controls of normal serum or antiserum specific to a heterologous antigen were run. Positive anti-

tissue localizing activity was shown by a significantly greater localization in the tissue from the antitissue serum than from the controls. The background radioactivity was reduced by labeling only the globulin fractions of the antiserum.

It has been possible by the use of such labelled antisera to show that antibodies present in antisera prepared against kidney tissue localize to a high concentration in the kidney with some localization in the liver, and antibodies in sera prepared against lung tissue localize primarily in the lung and kidney. In these experiments the antisera were prepared by injecting rabbits with rat lung or kidney tissue. The globulin fractions were obtained by fractionation with alcohol or ammonium sulfate and were labeled by iodinating with iodine containing I^{131} or by coupling with diazotized *p* sulfanilic acid containing S^{35} .

The duration of the radioactivity which localized in the kidneys indicated that the half life of the localizing antibody in the kidney is of the order of 20 days (5). Thus it appears that the antibody localizing in the kidney is fixed in such a manner that it cannot be metabolized by the cells. Moreover the radioantibody is localized very rapidly, within a single passage through the kidney (6), and the localization takes place primarily in the glomerular tuft (3).

Because of the rapidity of the localization, the localization must take place on some structure on which there is very extensive and complete contact between the blood stream and antigen responsible for the localization. Such contact probably obtains only between the blood and the vascular bed of the organ showing specific localization. Moreover the localization probably takes place on the surface of the cells responsible for this localization. Further evidence supporting this assumption is that the antigen in kidney tissue which causes the localization is insoluble in saline.

We have shown that the antisera prepared against whole kidney tissue contain antibodies which will react with soluble components of kidney tissue and antibodies which can react with insoluble components (7). However it is only

those which react with insoluble components which are responsible for the localization effect. The nonlocalizing antibodies are probably formed against the soluble components of the kidney which are apparently intracellular and the corresponding antibody molecules are nonlocalizing since they apparently do not pass through cell membranes rapidly enough to combine to any large extent with the internal antigens. The parallelism between the properties of the localizing antibody and the nephrotoxic factor is reported by others indicates the identity of these antibodies.

Recently we found that it is possible to elute the antibody which has localized and that this purified antibody can go specifically to the tissue from which it was prepared (8). Thus anti-rat-kidney antibodies eluted from the kidneys of rats receiving radioiodinated anti-rat-kidney serum goes to the kidneys of recipient rats to the extent of 10 per cent whereas only about one-half per cent of the original radioactivity localized in the kidney of the donor rat. However there are also antibodies in anti-rat-kidney serum which localize somewhat in the liver and lung. When

the antibodies are eluted from these organs they have the property of returning to the kidney and also to the organ of the original localization. Thus, radioactivity originally localized in the liver, after elution, goes back to the liver and kidney, while material originally localized in the lung goes back to the lung and kidney. All of these antibodies were originally prepared against the kidney. Similar results were obtained with specific purification of antilung antibodies. The localization in the various tissues reflects the heterogeneity of the antibodies.

That the different organs tested can fractionate the antiserum and preferentially remove certain antibody components indicates differences in the vascular beds of these organs which can be observed with the techniques described here.

In those perivascular diseases which appear to have an etiology of autoimmunization it may well be that the damaging antibody is antibody to the vascular bed of the tissue affected and this damaging antibody localizes as rapidly as it is formed. The specificity of the vascular bed would then determine which organ is affected.

*Symposium on Hemagglutination by Viruses Which Do
Not Specifically Elute¹*

Chairman GEORGE K HIRST

IN VITRO REACTIONS OF PNEUMONIA VIRUS OF MICE (PVM)

HAROLD S GINSBERG

From the Hospital of The Rockefeller Institute for Medical Research, New York City

PNEUMONIA virus of mice (PVM), a latent infectious agent, may produce extensive viral pneumonia and often death in its natural host, the mouse (1). The study of the pneumonia produced by this agent as an experimental model for the study of a viral respiratory disease (2-4) has been materially aided by the demonstration by Mills and Dochez (5) that this pneumotropic virus, under proper conditions, produces hemagglutination of mouse red blood cells. In addition, this phenomenon has permitted detailed investigation of the reactions between PVM and host cells (2, 6-8). This paper will be concerned with these reactions and the essential factors involved.

Tissue fluid expressed from whole (5) or sliced (9) PVM-infected lungs produces agglutination of mouse RBC, whereas suspensions of ground infected lungs do not clump erythrocytes. However, if such lung suspensions are heated at temperatures from 65° to 80°C for proper periods of time (2, 5), hemagglutination of added mouse RBC results. Addition of fresh mouse lung suspension again inhibits the agglutination reaction. This phenomenon can be repeated indefinitely without altering the virus. When heated PVM and mouse RBC are mixed and aliquots removed at intervals, it is readily shown (2) that not only does virus combine with the erythrocytes, but also that spontaneous dissociation does not occur. This is at variance with the influenza-mumps-NDV group of viruses which do release themselves from the bound state (10). These facts suggest that, although virus may be in a free state in the intact lung, disruption of the cells results in combination of PVM with a heat labile cell component. The fact that viral preparations which do not produce agglutination

of mouse RBC are not filterable through Coors no 3 filters, and are readily sedimented by high speed centrifugation, whereas preparations which hemagglutinate mouse RBC are readily filtered but cannot be easily sedimented in high gravitational fields (6, 9) is evidence that PVM actually combines with tissue particles. PVM in the combined state is much larger than the free viral particle, of the order of 140 m μ as compared with 40 m μ (9). That the particles which react with mouse RBC are indeed PVM particles has been established (2).

Dissociation of PVM from tissue component can be accomplished not only by heat or high pH (2, 6), but also, as indicated in table 1, by reducing the electrolyte concentration of the suspension (8). Thus, preparation of PVM-infected mouse lung suspension in distilled water or 0.25 M dextrose or sucrose permits direct hemagglutination of mouse RBC, and the free virus is fully infectious. The addition of NaCl to 0.15 M concentration results in combination of virus and cellular material which indicates that the reduced electrolyte concentration does not alter the capacity of either the virus or lung particles to combine. Furthermore, repeated dissociation and association of the PVM-cell component complex can be accomplished. A similar dependence upon the electrolyte concentration and pH is observed for the PVM-mouse RBC complex (8). The ionic requirements are not specific, either mono- or bivalent cations can be employed without influencing the capacity of lung particles or mouse RBC to bind virus. When free infectious virus is employed to demonstrate PVM-RBC combination, the virus remains infectious when converted again to the free state. Furthermore, the RBC are unaltered by combination with virus, and subsequently show undimin-

¹ May, 2, 1951, Cleveland, Ohio

ished capacity to recombine with virus. Sequential cycles of combination and dissociation of PVM and mouse RBC can be repeated at will by appropriate regulation of the electrolyte concentration and pH of the mixture (8). In contrast, the influenza-mumps-NDV group of viruses irreversibly alter the cell surface of erythrocytes with which they combine, and subsequent combination of virus with the same cells does not occur (10).

Early investigations (2, 7) suggested that PVM combined only with a component in those lung tissues which are susceptible to infection with this agent. Subsequent studies (11), employing more sensitive methods, indicate that, although combination is greatest with particles from cells which are susceptible to infection, PVM can nevertheless combine with a number of mammalian tissues in which this virus does not multiply.

TABLE 1. PREPARATIONS WHICH YIELD PNEUMONIA VIRUS OF MICE IN VARIOUS STATES

STATE	PREPARATION
1 Free infectious	Infected lung—squeeze Infected lung—slice—squeeze Infected lung suspension with <0.01 M electrolyte
2 Free noninfectious	70°C/30 minutes pH 11.0
3 Combined infectious	Infected lung suspension with >0.1 M electrolyte
4 Combined noninfectious	'2' + fresh lung particles

TABLE 2. PROPERTIES OF PNEUMONIA VIRUS OF MICE (PVM) IN RELATION TO ITS STATES

STATE OF VIRUS	PROPERTIES						
	Infectivity mice	Hemagglutination		Combination with lung particles	Specific complement fixation	Specific antigenicity	Size μ
		Unheated	After 70°C				
Free infectious	+	+	+	+	+	+	40
Free noninfectious	0	+	+	+	+	+	40
Combined infectious	+	0	+	0	0	+	140
Combined noninfectious	0	0	+	0	0	+	140

In not a single instance, however, has it been possible to demonstrate the association of PVM with tissue of the chick embryo, an animal completely resistant to infection with this virus (2, 7). Combination between PVM and various adsorbents is likewise demonstrable (11). The combination of PVM with tissue particles or RBC appears to be more dependent upon the ionic composition of the milieu than is the formation of similar complexes by the influenza viruses (cf table 3) (8).

It is now clear that PVM may be obtained in four separate and distinct states: 1) free infectious, 2) free noninfectious, 3) combined infectious, and 4) combined noninfectious (6). The methods by which virus in each state may be obtained are summarized in table 1. Experimental data suggest that for the most part PVM exists in the infected mouse lung in the 'free infectious' state, but whether the other states exist naturally in the infected host has not been determined. Certain data (12) suggest that an infected mouse lung suspension which is able to produce a pro-

gressive infection in the mouse contains both infectious and noninfectious viral particles, both of which produce agglutination of mouse RBC. Table 2 summarizes some of the biologic and physical properties of the viral particles in each state. Although the mechanism by which PVM in the combined infectious state produced infection in the mouse lung was initially puzzling, it has been demonstrated that the lung possesses an enzyme which liberates infectious virus from the combined state (7). The free infectious virus may then combine with susceptible host cells, invade these cells, and multiply to form new particles which then lead to pneumonia (3).

It is evident that the reactions between PVM and tissue particles or mouse RBC are different from those of the influenza-mumps-NDV viruses with comparable cells. Some of these reactions are summarized and compared in table 3. It will be noted that neither inactivated animal nor human sera contains a substance, other than antibody, which reacts with PVM to inhibit combination with mouse RBC, whereas the pres-

ence of such nonspecific inhibitors of hemagglutination by influenza viruses has been widely observed (13) The other reactions likewise clearly

mumps virus interferes with the multiplication of PVM but not with influenza viruses in the mouse lung (15)

TABLE 3 COMPARISON OF CERTAIN REACTIONS OF PNEUMONIA VIRUS OF MICE (PVM) AND INFLUENZA VIRUSES

REACTION	PVM	INFLUENZA
Reaction with RBC	Mouse, hamster	Chick +
Combination RBC and tissue particles	+	+
Spontaneous dissociation	0	+
Virus alteration of 'binder'	0	+
Chemical nature of 'binder'	Protein	Mucoprotein
Electrolyte requirement		
Combination	>0.10 M	>0.0015 M
Dissociation	<0.01 M	
Enzymatic inactivation of 'binder'	Trypsin	RDE (<i>V. cholerae</i>)
Enzymatic inactivation of virus	Trypsin, chymotrypsin	0
'Binder' in serum	0	+

denote the marked differences in biological activities of these viruses. It appears that these viruses have dissimilar host cell requirements for multiplication. 1) the influenza viruses do not interfere with the multiplication of PVM in the mouse lung, nor does PVM preclude the multiplication of the influenza viruses (14), and 2)

DISCUSSION

It has been clearly demonstrated that viruses, animal (8) and bacterial (16), can combine with inorganic materials such as celite and glass, and as such represent artificial complexes. Adsorption of certain viruses to mammalian and fowl RBC may in a sense be equally as artificial a reaction. In certain instances the reaction between virus and erythrocyte has been argued, by analogy, to be similar to or identical with the reaction between virus and the susceptible host cell which supports viral multiplication. That such is not the case with certain neurotropic viruses, GDVII (17), SK-MM group (18), and Japanese B viruses (19), appears probable. By altering the environmental conditions in the test tube, combination of these viruses with the surfaces of certain RBC has been accomplished and agglutination of the erythrocytes occurs. The chemical nature of the surface of the RBC and the chemical constitution of the virus probably dictate the environmental factors required to produce the RBC-virus complex.

Although combination between virus and tissue components or adsorbents may occur in a purely physical sense, it does not follow that certain cell surface constituents are not necessary for combination *in vivo*. Indeed, infection may be limited to those cells which by virtue of their chemical constitution permit cell-virus combination under the environmental conditions which prevail in the host.

HEMAGGLUTINATION BY VIRUSES AFFECTING THE HUMAN NERVOUS SYSTEM¹

ALBERT B. SABIN

*From The Children's Hospital Research Foundation, Department of Pediatrics,
University of Cincinnati College of Medicine, Cincinnati, Ohio*

DURING the past 18 months, Doctors Edward L. Buescher, Robert M. Chanock and I have succeeded in demonstrating and elucidating some of the properties of the hemagglutinins associated with the viruses of Japanese B (Jap B) encephalitis, St. Louis (SLE) encephalitis, West Nile fever and Russian Spring-Summer (RSSE) encephalitis. While each hemagglutinin possessed distinct properties and presented special problems, certain general principles were found to apply to the entire group.

1) Strains of virus which have had a great many passages in mice (over 100) have failed to yield hemagglutinin by methods which proved successful for strains which have had fewer passages.

2) The electrolyte content and pH of solutions used for extraction of infected mouse brains have determined not only the recovery of demonstrable agglutinin, but also the subsequent stability of that which is recovered. Thus, it has been found necessary *not* to use distilled water, hypotonic buffers, or physiologic salt solution buffered just to the acid side of neutrality, since these extract enough inhibitor to obscure the hemagglutinin. It was also necessary to avoid extraction by means of the Waring blender. Centrifugation of the 0.9 per cent NaCl extract at 13,000 rpm for 1 hour (approximately $20,000 \times g$) removed particles, which destroyed the Jap B hemagglutinin within about 3 days at 4°C, but left behind another substance capable of destroying the SLE hemagglutinin within about 2 days. A stable SLE hemagglutinin was obtained only after it was found that the substance which destroyed it was most active on the acid side of pH 7.6 and practically inactive at about pH 8.0.

3) The reactions of this whole group of hemagglutinins are markedly influenced by pH, each

one having its own optimum narrow zone for reaction with the red cells. However, in the case of the SLE hemagglutinin it was found that this pH zone progressively broadened and shifted to the alkaline side as the preparation 'aged' on storage in the refrigerator.

4) The red cells of choice for the Jap B, SLE and West Nile hemagglutinins are derived from newly hatched chicks, while those from older chicks, chickens, and sheep give lower titers, irregular or negative results. The RSSE hemagglutinin thus far has reacted only with sheep cells. Although these viruses are pathogenic for human beings and rhesus monkeys, they do not hemagglutinate their erythrocytes.

5) The hemagglutinins associated with this group of viruses are all highly unstable at 37°C, and to a varying extent, depending on the virus and the pH, also at room temperature and 2°C. The SLE hemagglutinin is much more unstable than that of Jap B. Thus, it was impossible to obtain reproducible or reliable results in hemagglutination inhibition tests with SLE virus, until it was found that at 2°C and at pH 6.9, which was optimum for hemagglutination, the diluted hemagglutinin was destroyed within the brief time required to distribute it in a series of tubes, and appropriate modifications in technique were instituted to overcome this difficulty.

6) All normal sera were found capable of inhibiting these hemagglutinins in dilutions as high as 1:2,000 or more, the titer varying with the species, individuals within the species, and, of course, the amount of hemagglutinin in the test. This may be contrasted with the absence of such normal inhibitor for the hemagglutinin of encephalomyocarditis virus (MM, Columbia Sk). The inhibitor in normal serum behaves like soluble receptor substance, and is present in abundance in animals whose erythrocytes have no receptors for these hemagglutinins. The normal inhibitor for the Jap B, SLE and West Nile hemagglutinins is either lipid or lipoprotein because it proved possible to remove it by extrac-

¹ Aided by a grant from the Commission on Virus and Rickettsial Diseases, Armed Forces Epidemiological Board.

tion of serum with chloroform, benzene, ether, etc., or by precipitation of the protein with acetone. Since specific antibody was unaffected by these procedures, it became possible to measure it without interference from the normal inhibitors in the serum.

7) No receptor-destroying enzyme was found to be associated with the Jap B, SLE and West Nile hemagglutinins. However, hemagglutination could be reversed by repeated shaking at room temperature or 37°C, reversal occurring first in the mixtures containing the smallest amount of hemagglutinin. There is evidence that the reaction between hemagglutinin and the receptors on the red cells is of the equilibrium type. Accordingly, as the uncombined hemagglutinin is destroyed at room temperature or 37°C, particularly on the acid side of neutrality, more hemagglutinin is dissociated from the erythrocyte receptors, and hemagglutination is reversed. That the receptors are unaffected in this reaction is evident from the fact that the erythrocytes are readily reagglutinated by the addition of fresh hemagglutinin.

PROPERTIES AND REACTIONS OF THE JAP B HEMAGGLUTININ (1)

Hemagglutination has been demonstrated with each of 9 different strains of this virus, which have had from 4 to about 70 passages in mice. The Nakayama strain, which in its 70th to 80th passage yielded the optimum titers of hemagglutinin, gave completely negative results with material which had had 183 or more passages in mice. Potent preparations with titers as high as 1:10,000, which remain stable for many months in an ordinary refrigerator at about 5°C, can be prepared as follows. The infected mouse brains, washed free of blood, are ground in a mortar with unbuffered 0.9 per cent solution of NaCl to form a 20 per cent suspension. After extraction in the cold for a period of 4 to 12 hours, the suspension is centrifuged in the cold at 13,000 rpm for one hour (about 20,000 × g), and the supernatant liquid is stored at 5°C. Centrifugation at only 2,000 rpm for 10 to 20 minutes leaves particles in the supernatant liquid which completely destroy the hemagglutinin in about 4 days at 5°C and more rapidly at higher temperatures. Removal of these particles not only yields a preparation that is stable in the cold but one whose titer frequently increases 4- to 16-fold during the first week of storage. Hemagglutina-

tion occurs only in the pH zone of 6.3 to 7.1 and optimally at pH 6.5 to 6.8. Hemagglutination also occurs when the dilutions are made in unbuffered 0.9 per cent NaCl, but the resulting titers vary markedly with different preparations, with period of storage, and other, as yet, undetermined factors. When appropriately buffered, 0.9 per cent NaCl solution is used for preparation of the dilutions, e.g. M/50 or M/100 phosphate at pH 6.5, titers are enhanced as much as 4- to 100 fold, again varying with the type of preparation, period of storage, erythrocytes used etc. This enhancement does not occur when the dilutions are first prepared in unbuffered 0.9 per cent NaCl, and immediately thereafter adjusted to the optimum pH and buffer concentration prior to the addition of erythrocytes. There is no indication that the unbuffered salt solution is deleterious to the hemagglutinin, it appears rather as if the appropriate buffer and pH causes an unfolding or depolymerization of the hemagglutinin. As a matter of fact after storage in the refrigerator for a month or longer as an ordinary saline extract certain preparations undergo a change whereby dilution in unbuffered 0.9 per cent NaCl gives the maximum high titers without any enhancement by buffers at optimum pH. The absence of hemagglutination immediately outside of the required pH zone is not due to rapid destruction of the hemagglutinin, but rather to failure of combination with the erythrocytes. Hemagglutination cannot be reversed by resuspending the agglutinated, sedimented erythrocytes in solutions having a pH outside the required zone.

A 0.25 per cent suspension of chick cells is used (final concentration of 0.125%) because it yields the highest titers. In solutions properly buffered for optimum dispersion of hemagglutinin (H) and combination with receptor (R), the hemagglutinin titer diminishes in a constant ratio as the concentration of erythrocytes increases. Thus, when the dilutions are made in 0.9 per cent NaCl containing M/50 phosphate at pH 6.5, the titer increases 4-fold as the concentration of erythrocytes, in the range of 2 per cent to 0.25 per cent, is decreased 2-fold. These data, as well as those on reversal of hemagglutination without change in the receptors, suggest that the reaction between H and R is of the equilibrium type which may be expressed as $H_x + R_y \rightleftharpoons H_xR_y$, and that the number of R on a single erythrocyte combined with H varies with the concentration of H and the number of erythro-

cytes in the mixture. The lower titers with the more concentrated suspensions of erythrocytes also indicate that a minimum number of R on each cell must be combined with II to result in hemagglutination. It is also worth noting here that, in several simultaneous experiments, the enzymes of *Vibrio cholerae* destroyed the receptors for influenza virus on the chick erythrocytes, but were without effect on the receptors for the Jap B hemagglutinin.

Normal sera from human beings, monkeys, rabbits and mice inhibited hemagglutination, even after the pH was adjusted to the optimum zone required by the hemagglutinin of Jap B virus. The inhibitor in the normal sera reacts with the hemagglutinin in precise multiple proportions giving a straight line relationship with a slope of 1. The inhibitor can reverse the hemagglutination of cells which had combined with small amounts of hemagglutinin (5U or less), and behaves as if it were either the receptor substance of the erythrocytes in soluble form or a substance having an affinity for the same combining groups on the hemagglutinin. The normal inhibitor cannot be removed by dialysis. It is not affected by heating at 65°C, and boiling for 15 minutes does not appreciably alter the inhibitory titer of rabbit and mouse sera but reduces the titer of human serum as much as 75 per cent. The lecithinase of *Clostridium perfringens* toxin, in the presence of CaCl₂, does not destroy the inhibitor but abolishes its resistance to boiling. Treatment with periodate or strong proteinases does not destroy the inhibitor. However, extraction with lipid solvents (ether, benzene, ethylene chloride, chloroform) or precipitation with acetone largely or completely removes the inhibitor from rabbit and human serum and only partially from mouse and monkey serum. Chloroform extraction yields the best results, removing at least 95 per cent of the inhibitor but leaving specific antibody in undiminished titer.

The reaction between specific antibody and the Jap B hemagglutinin also gives a straight line relationship but with a slope of <1, thus differing from the direct proportionality obtaining in the reaction with normal inhibitor. Preliminary observations have indicated that the hemagglutination inhibition produced by specific antibody can be utilized for both diagnostic and epidemiologic survey purposes.

The Jap B hemagglutinin is very heat-labile. At pH 6.5 it becomes inactive at 37°C within

30 minutes, while at pH 7.1 inactivation is only slightly slower. At a room temperature of 24° to 25°C inactivation proceeds at a regular rate somewhat more slowly. At pH 7.0 to 7.1 the activity persists for months at about 4°C. These data apply to 13,000 rpm supernates from which the inactivating substance or enzyme associated with the particles sedimented at this speed has been removed, before removal of this substance inactivation proceeds more rapidly at all temperatures and is complete a few days at 4°C. The effect of freezing and thawing and of lyophilization differs in uncentrifuged and centrifuged preparations as shown in table 1.

The marked instability of the hemagglutinin is also apparent in the fact that mere bubbling of nitrogen gas through 13,000 rpm centrifuged 20 per cent suspension, diluted 1:16 in 0.01 M

TABLE 1. EFFECT OF FREEZING AND THAWING AND LYOPHILIZATION ON JAP B HEMAGGLUTININ

PROCEDURE	20% JAP B MOUSE BRAIN SUSPENSION	
	Uncentrifuged	13,000 rpm supernate
Frozen and thawed once	Active	Inactive
Frozen and thawed 5 ×	Inactive	Inactive
Lyophilization	Inactive	Active

borate-saline buffered at pH 6.8 and kept in an ice bath, was enough to inactivate 75 per cent of it in 5 minutes and 96 per cent in 20 minutes, without significant alteration of pH.

Ultracentrifugation and gradocol membrane filtration experiments indicate that the Jap B hemagglutinin is not smaller than the infectious particle. There is rather a possibility that it may be larger. Centrifugation at 31,440 rpm (average of 58,300 × g) which almost completely sediments the infectious particles, also removes all of the hemagglutinin from the supernatant liquid. Although 75 per cent of the hemagglutinin is removed from the supernatant liquid after centrifugation at 21,740 rpm (average of 27,950 × g), it is difficult to correlate this with the behavior of the infectious particles, because titration of infectivity is not sufficiently accurate within these limits. However, while the average pore diameter (APD) of the membrane, which just allows minimal amounts of infectious virus

to pass, is 50 $m\mu$, and while almost all of the infective particles pass membranes with an APD of 100 $m\mu$ or larger, the hemagglutinin was demonstrable in filtrates from membranes with an APD of 260 $m\mu$ or larger, but not from those with an APD of 200 $m\mu$ or less

Of special interest is the effect of certain simple chemical compounds and of certain bacterial products on the Jap B hemagglutinin. Thus, $ZnSO_4$, which had no effect on hemagglutination by influenza virus, was capable of inhibiting the Jap B hemagglutinin in amounts of 0.03 to 1.92 μg per unit, the more dilute solutions requiring more Zn per unit. It was found that in the concentrations used, the zinc had no effect on the red cells but combined with the hemagglutinin (H) in an equilibrium type of reaction, which may be expressed as

It was possible to reverse this reaction by dilution and by careful removal of Zn from the mixture with H_2S . The experiments with zinc were carried out with collidine or borate buffers. A suitably buffered solution of diethyl, dithio carbamate inhibited the Jap B hemagglutinin in a final concentration of 1:2,000, while 8-hydroxyquinoline and α, α' dipyridyl which also bind heavy metals (although not as well in the presence of proteins) were without effect in 20 times greater concentration. Partially purified preparations derived from cultures of *Clostridium histolyticum* and *Clostridium lentoputrescens*, after boiling for 15 minutes, inhibited the Jap B hemagglutinin in dilutions as high as 1:1,000,000. The effect was on the hemagglutinin and not on the red cells. Further purification of the substances by Dr. A. A. Tytell indicated that the inhibitory activity was associated with certain nucleic acid or protein components which were different from the proteinase in these cultures.

PROPERTIES OF THE ST. LOUIS ENCEPHALITIS VIRUS (SLE) HEMAGGLUTININ

No hemagglutinin could be extracted from mouse brains infected with the Webster no. 3 strain of SLE virus which has had an unknown large number of passages since its isolation in 1933, but was found in several recently recovered strains kindly supplied by Dr. E. H. Lennette. However, the SLE hemagglutinin proved to be much more unstable than the Jap B, and little

work could be done with it until the physico-chemical factors responsible for its rapid degradation were discovered (2). The hemagglutinin is now prepared by extracting the washed, infected mouse brains with enough M/64 borate buffer of pH 9.0 in 0.9 per cent NaCl to yield a 20 per cent suspension. After centrifugation in the cold at 13,000 rpm for one hour, the supernatant liquid has a pH of 8.0 to 8.1 and hemagglutinin titers as high as 1:2,560.

Although hemagglutination occurs with both sheep and chick erythrocytes, 0.25 per cent suspensions of red cells obtained from newly hatched chicks give the best results. The test is performed at room temperature, although 4°C is also suitable. With a fresh preparation, a pH of 6.7 is usually optimum and negative results are the rule beyond pH 7.0. As the preparation is aged on storage at 4°C the pH zone for hemagglutination progressively shifts to the alkaline side and broadens to a point where after a period of about 30 days the reaction occurs best between pH 6.9 and 7.8. At pH 7.0, the SLE hemagglutinin (13,000 rpm supernate + equal volume of phosphate buffer) was destroyed within 5 minutes at 37°C and within 10 to 20 minutes at 24°C, while at 1°C it lost 85 per cent of its activity within 5 to 10 minutes. At pH 7.9, on the other hand, the activity persisted in undiminished titer for at least 160 minutes at 24°C, but was still destroyed within 5 to 10 minutes at 37°C. No receptor destroying enzyme was found, but hemagglutination could be reversed by shaking the tubes, the extent of reversal being influenced by pH, temperature and time. Normal sera contain inhibitor which reacts with the SLE hemagglutinin in the same manner as with that of Jap B. Acetone precipitation proved to be superior to chloroform extraction for elimination of this inhibitor, and the precipitated protein contained the specific antibody in undiminished titer. Tests on acute and convalescent sera from 9 patients with St. Louis encephalitis (kindly supplied by Dr. E. H. Lennette), as well as on 50 normal sera, showed that the hemagglutination inhibition test can be used for diagnostic purposes.

HEMAGGLUTININ OF WEST NILE FEVER VIRUS

Although only exploratory work has been done thus far with this virus, a hemagglutinin was obtained in 0.9 per cent NaCl extracts of in-

fect mouse brains which reacted with chick and sheep erythrocytes at a pH of 7.0 to 7.5 (optimum about 7.3) at room temperature. It was thus apparent that the three antigenically related viruses could be differentiated by the pH zones in which they produced hemagglutination (see table 2). Since the pH zone changes markedly for 'aged' SLE hemagglutinin and possibly also for that of West Nile, the data shown in table 2 apply only to relatively fresh preparations.

Little work has been done thus far on the physico-chemical factors which influence the stability and behavior of the West Nile hemagglutinin, but a peculiar phenomenon was observed with reference to the temperature requirements

allowed to sediment at 4° C. Chloroform extraction removed the normal inhibitor and anti-West Nile sera produced specific inhibition. A common antigen between the Jap B, SLE and West Nile hemagglutinins was also demonstrated by hemagglutination inhibition tests with chloroform extracted sera.

HEMAGGLUTININ OF RUSSIAN SPRING-SUMMER ENCEPHALITIS (RSSE) VIRUS

Infected mouse brains extracted for several hours in unbuffered 0.9 per cent NaCl, yielded preparations which hemagglutinated sheep erythrocytes (but not chick, human 'O' or rhesus) at pH 7.5 (but not pH 5.5, 6.5 or 8.5) and at room temperature (26° C) but not at 4° C. These properties differentiate it not only from the hemagglutinins of Jap B, SLE and West Nile viruses but also from that of the encephalomyocarditis-MM-Columbia Sk virus. Preliminary observations suggested the possibility that the RSSE hemagglutinin, unlike those of Jap B, SLE and West Nile, may destroy the receptors on the sheep cells. Normal sera had inhibitory activity which could *not* be removed by extraction with chloroform. While normal guinea pig serum had an inhibitory titer of 1:20, anti-RSSE guinea pig serum had an inhibitory titer of 1:160. The RSSE hemagglutinin is very unstable at pH 7.0 to 7.1, even at 4° C, and much more work remains to be done with it.

TABLE 2 DIFFERENTIATION OF ANTIGENICALLY RELATED VIRUSES BY pH ZONE OF HEMAGGLUTINATION

VIRUS	HEMAGGLUTINATION AT INDICATED pH		
	6.5	6.7	7.4
Japanese B	++++	+++	0
St. Louis	0 to ±	+++	0
West Nile	0	0	+++

TABLE 3 INFLUENCE OF TEMPERATURE ON HEMAGGLUTINATION OF CHICK ERYTHROCYTES BY STORED OR FROZEN AND THAWED WEST NILE HEMAGGLUTININ

TEMPERATURE OF REAGENTS AT TIME OF MIXING	TEMPERATURE FOR SUBSEQUENT SEDIMENTATION OF ERYTHROCYTES	RESULT
25° C	25° C	Negative
25° C	4° C	Positive (1:2560)
2°-4° C	4° C	Negative

for the reaction between stored hemagglutinin and chick cells (see table 3).

Other tests also indicated that while 25° C was required for initial combination, 4° C was required for appearance of hemagglutination. It should be noted, however, that this phenomenon obtained only for *stored or frozen and thawed* hemagglutinin and chick cells, since fresh preparations hemagglutinated both chick and sheep cells at 25° C and stored or frozen and thawed preparations still agglutinated sheep cells at 25° C. However, higher titers were obtained when mixtures prepared at room temperature were

HEMAGGLUTININS FOR WESTERN (WEE) AND EASTERN EQUINE ENCEPHALITIS (EEE) AND POLIOMYELITIS VIRUSES

Extraction with unbuffered, 0.9 per cent NaCl has thus far yielded no hemagglutinin for multiple-passaged and recently recovered strains of EEE, WEE, and poliomyelitis viruses in surveys utilizing chick, sheep, rhesus and human type 'O' erythrocytes and diluents buffered at pH 5.5, 6.5, 7.5 and 8.5. One recently recovered WEE strain gave suggestively positive results with chick and sheep cells at pH 5.5 at room temperature, but this observation has not yet been followed up. Extracts of several recently recovered strains of poliomyelitis virus, centrifuged at 2000 rpm, regularly produced hemagglutination of human type 'A' and 'O' cells (but not of chick or sheep cells) at pH 5.4 to 6.2 and at 37° C, but not at room temperature or 4° C. While extracts of normal monkey cords were negative under the

same conditions, the hemagglutination could not be inhibited by specific antiserum and appeared to be due to a substance in the infected tissue with an isoelectric point in this particular pH zone. At the moment it is difficult to indicate the procedures or conditions which may lead to the

demonstration of hemagglutinin for the polio-myelitis group of viruses. From what has been presented thus far, however, it is clear that the viruses affecting the human nervous system provide an interesting field for future studies on hemagglutination.

HEMAGGLUTINATION BY GDVII AND THE COL SK, COL MM, MENGO ENCEPHALOMYELITIS AND ENCEPHALOMYOCARDITIS VIRUSES

ROBERT H. YAGER¹

From the Veterinary Division, Army Medical Service Graduate School, Washington, D C

THE AGGLUTINATION of sheep erythrocytes by Col SK and Col MM viruses first was reported in 1947 by Hallauer (1) Olitsky and Yager (2) extended this work by not only confirming the findings of other investigations but by adding the viruses of encephalomyocarditis and Mengo encephalomyelitis. At the same time, Lahelle and Horsfall (3) reported that the GDVII strain of mouse encephalomyelitis virus would agglutinate human O cells in the cold. Later Verlinde and de Baan (4) and Bremer (5) also showed positive sheep cell hemagglutination by Col SK and Col MM viruses. This series of papers (1-5) brought to light for the first time the fact that several neurotropic viruses would cause the agglutination of certain erythrocytes under very exacting requirements of incubation temperatures and that such hemagglutinations were specific in that hemagglutination inhibition (HI) could be demonstrated when immune serum was added in the usual HI test. Interest was thus stimulated to discover other neurotropic viruses capable of agglutinating erythrocytes. Results of the work of Verlinde and de Baan (4) and of Sabin and Buescher (6) have now extended this list of viruses to include Japanese encephalitis, St. Louis encephalitis and others, each of which has its own peculiarities of temperature of incubation, preparation of the antigen, type of cells agglutinated and the pH range. It is believed that the future may reveal other neurotropic viruses to agglutinate erythrocytes provided the exacting conditions for each are discovered.

Lahelle and Horsfall (3) demonstrated that the GDVII strain of mouse encephalomyelitis virus would agglutinate human O red cells at 4° C but not at 23° C or 37° C, that the hemagglutination was inhibited by homologous immune sera and by FA antiserum but not by antiserum against other neurotropic viruses. They failed to demonstrate that FA virus would agglutinate

any of the erythrocytes tested under their experimental conditions.

Lahelle and Horsfall (3) observed that where GDVII virus is readily adsorbed by human O erythrocytes at 4° C, it was quickly eluted from them at 37° C and that this adsorption and elution could be carried on an indefinite number of times. By taking advantage of this property, it was possible to effect about a 10-fold concentration.

Fastier (7) investigated the mechanism of GDVII hemagglutination by heating the antigen to 56° C for 30 minutes. This reduced the titer considerably but did not influence the adsorption and elution process with human O red cells. Unlike PR8 influenza virus, treatment of human O cells with periodate had very little effect on the elution of GDVII virus. In addition, extracts of human O cells inhibited influenza hemagglutination to a much greater degree than was apparent for the GDVII strain. He concluded that the mechanism of hemagglutination of GDVII and PR8 were not closely related. Fastier (8) later investigated the inhibition of GDVII virus hemagglutination by normal tissue extracts. He concluded that saline extracts of normal mouse organs were, in some varying degrees, capable of inhibiting GDVII virus hemagglutination. Sera deriving from the mouse, rat, guinea pig and rabbit exhibited this property to the largest extent. The inhibitor present in mouse brain and serum reacted similarly to the effects of heat and other agents tested. Studies on the distribution of the inhibitor revealed that fetal mouse brains and adult tissue contained comparable amounts. Fastier showed that the inhibitor could be extracted in saline solution, further, that this material could be concentrated by 50 per cent saturation with ammonium sulfate at pH 7.0. This extract appeared to be incapable of inactivating GDVII virus when used in place of immune serum in neutralization tests.

Before beginning a discussion of the Col MM, Col SK, encephalomyocarditis and Mengo en-

¹ Lieutenant Colonel, Veterinary Corps

cephalomyelitis viruses, it should be pointed out that Warren and Smadel (9) and Dick (10) have published conclusive evidence that these viruses, probably indigenous in rodents, are identical, such evidence being based on the results of neutralization, complement-fixation and cross-immunity tests. Therefore, in this presentation, these viruses will be referred to as the EMC group as suggested by Warren and Smadel (9).

Each of the viruses of the EMC group will agglutinate sheep cells at 4° C and will elute if the temperature of incubation is raised above 20° C. Like GDVII hemagglutination such adsorption and elution may be carried on an indefinite number of times and this method may be employed to concentrate the virus. Homologous immune sera will inhibit hemagglutination as well as heterologous immune sera prepared against any of the members of the group. Thus the cross-hemagglutination inhibition (HI) test provides further serologic evidence of their identities.

Gard and Heller (11) working with the Col MM strain of the EMC group have attempted to refine the method employed and standardize a technique of determining HI titers in human sera, a tool to be used to determine the importance of the disease in human beings. A very dilute erythrocyte suspension, 0.05 per cent, was employed to increase sensitivity and the resulting loss of stability was overcome by the addition of an extract of sheep brain in the place of bovine plasma albumen employed by Olitsky and Yager (2). A 10 per cent sheep brain extract clarified by centrifugation at 12,000 *g* was employed as the diluent for the virus propagated in mouse brain. These authors failed to find inhibitors similar to those reported by Sabin and Buescher (6), effective against Col MM hemagglutinin in either infected or normal brain tissue. Hemagglutination was not inhibited by pseudomucinous ovarian cyst fluids which evidenced high inhibitory activity against influenza virus hemagglutinin. In addition, and unlike Japanese encephalitis virus (6), Col MM was shown to be independent of pH range (6.0-9.0). However, ionic composition of the suspending medium was a factor since hypertonic salt solutions suppressed hemagglutination. The presence of positive or negative ions in solution, exerted much greater influence. It was shown that mono- and divalent cations had no obvious effect. On the other hand, multivalent anions caused considerable inhibition about proportional to their charge. Four units of virus would be completely inhibited in the standard HI test by

0.0002 M hexametaphosphate. Evidence was brought forth to show that this action was on the red cell rather than upon the viral particles. For example, if the number of units of virus were increased in the HI test, a corresponding decrease in the HI titer of the serum was observed. On the other hand, the HI titer of hexametaphosphate was independent of the number of units of virus employed to the HI test. In addition sodium hexametaphosphate failed to neutralize the Col MM virus in the standard neutralization test. Gard and Heller (11) propose the use of a standardized inactivated immune rabbit serum which like the test sera is adsorbed in the cold with sheep erythrocytes. The hyperimmune rabbit serum is, in addition, adsorbed with normal mouse brain. An HI test with adequate controls is conducted employing 0.2 ml of serial dilutions of serum, 4 agglutinating units contained in 0.1 ml. After incubation for half an hour at room temperature, 0.1 ml of a 0.2 per cent RBC suspension is added and the test is incubated at 4° C. Results are expressed as inhibiting activity in comparison to a standard serum and expressed as the HI index, since the HI titer of a serum is dependent upon the amount and state of the virus employed in the titration. An index of below 1 was classified as negative, 1 to 4 doubtful or weak and values above 8 were considered positive. Results obtained on 384 sera deriving from patients who exhibited CNS symptoms were examined and of this group 73.2 per cent were negative, 14.3 per cent weakly positive and 12.5 per cent positive. Of 39 sera deriving from patients with various diseases other than the involvement of the CNS, no positive reactions were obtained. The 146 sera obtained from blood donors and pregnant women were examined, and 88.4 per cent were negative, 10.9 per cent exhibited weakly positive results and 0.7 per cent were positive. Gard and Heller, however, point out that the positive sera failed to neutralize Col MM virus in the neutralization test and believe that the inhibiting capacity of the sera is not due to the presence of specific antibodies and is therefore, in its present state, not a usable tool for determination of past infection with a virus of the EMC group. On the other hand, since Warren, Smadel and Russ (9) have found antibody to the different members of this group in patients having a mild febrile illness, and since Seligmann and Jungeblut (12) have demonstrated positive neutralizing antibody against the Col SK virus

in normal sera, the question of whether positive reactions obtained by Gard and Heller may not have been due to inapparent or non-recognizable infection. Further work is needed to clear up this point.

Olitsky and Yager (2) attempted to discover other neurotropic viruses that would cause hemagglutination of erythrocytes. Eastern equine encephalitis, Western equine encephalitis, Venezuelan equine encephalitis, Japanese B encephalitis, St. Louis encephalitis, Russian Far East encephalitis, vesicular stomatitis (2 strains), Theiler (FA strain), Theiler (TO strain), poliomyelitis (Lansing strain) poliomyelitis (MEF1 strain), West Nile, rabies, lymphocytic choriomeningitis, herpes simplex and louping ill viruses were all tested for hemagglutinins using sheep, human O, chick, horse, hamster, dog, cat and guinea pig erythrocytes. In no instance was a specific hemagglutination observed that could be inhibited by homologous immune serum. Many nonspecific false or spontaneous hemagglutination reactions did occur, particularly when a mouse brain virus or normal mouse brain suspensions were employed with hamster cells (4). Normal and immune sera was shown to contain an inhibitor (HI) against this hamster hemagglutinin. In addition an agglutinin for dog, cat and guinea pig erythrocytes is contained in normal or virus-infected mouse brain suspensions.

Yager *et al.* (13) employing substantially the same technique used by Olitsky and Yager (2) attempted to extend the hypothesis that hemagglutination might depend upon selection of eryth-

rocytes deriving from a particular species of animal or bird since GDVII will agglutinate only human O cells and the EMC group only sheep erythrocytes. In the course of this investigation, erythrocytes deriving from 25 species were employed using eight viruses as antigens. In no case could a specific hemagglutination be demonstrated.

Bremer (5) demonstrated with reference to hemagglutination of sheep cells by Col SK and Col MM viruses that potassium (C_1) enhances agglutination while calcium (C_2) elutes the virus from the cells thus inhibiting agglutination.

Sabin and Buescher (6) have pointed out that in the case of Japanese encephalitis virus hemagglutination not only is the selection of an erythrocyte important as is the ionic state of the medium and also the pH range. In addition, continued passage in mice will cause the loss of the ability of the Japanese encephalitis virus to agglutinate red cells, so that a positive test will result only with viruses in the earliest mouse passages. This finding we have been able to confirm (14).

In conclusion, the EMC group and GDVII strain of Theiler virus will agglutinate erythrocytes, hemagglutination being inhibited by homologous immune serum, but in each of these instances, many variables are encountered and different conditions underlie the reactions. The demonstration of hemagglutination by additional neurotropic viruses is a possibility but the road to this achievement has many barriers as illustrated by the experience of the workers in this field.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS

Symposium on Growth of Bacterial Virus in the Host Cell¹

Chairman MARK ADAMS

MECHANISM OF BACTERIOPHAGE REPRODUCTION²

S E LURIA³

From Indiana University, Bloomington, Indiana

THE STUDY of phage reproduction centers around the question of how the specific material substrate of the virus is replicated in many copies inside the host cell. A number of approaches have been developed, some of which have been well illustrated by the reports presented by the other participants in this symposium.

The biochemical approach (1-3) analyzes the changes in amounts of gross chemical fractions of the virus-infected system (proteins, RNA, DNA), it studies the origin of virus components by isotopic and by nutritional methods, it follows the fate of the components of the infecting virus and of certain host cell components, particularly enzymes. The results from this approach to date indicate that the new virus is made from building blocks synthesized, partly before but mostly after infection, by the host enzymes, and that in all probability the only *specific* material to be formed in phage-infected bacteria (in infections normally leading to lysis rather than to lysogenicity, that is, to symbiosis between virus and bacteria) is virus material. Phage infection apparently allows the pre-existent enzymes of the host to pile up the building blocks, but redirects the specific organization of these towards its own ends.

We have recently obtained cytochemical data (4) that suggest a possible interpretation of the reorientation of specific syntheses by phage infection. Chromatinic staining of bacteria infected with the same phages used in the biochemical studies reveals an almost immediate disruption of the 'nuclear bodies' of bacteria after infection.

This is followed by a filling up of the cell with a finely granular type of Feulgen positive material (chromatin), which we tentatively identify with phage material because of its absence whenever infected bacteria fail to produce active phage, either because of genetic peculiarities of the host or because of pre-treatment of the phage, for example, with proper doses of radiation. Nuclear disruption itself, however, is always present whenever the bacterium is killed by the phage, whether active phage production follows or not. It seems reasonable to suppose that the peculiar 'killing' of bacteria by phage, which suppresses cell reproduction but not cell metabolism, is a direct consequence of the disruption of the nuclear, presumably genetic, apparatus of the bacteria. Furthermore, I wish to suggest that the redirection of the syntheses results from the replacement of the genetic apparatus of the host with that of the virus, under the influence of the new set of genetic determinants brought in by the virus, virus is produced instead of bacterial protoplasm. In particular, the failure to synthesize new bacterial enzymes, as illustrated by the lack of enzymatic adaptation (5), would result from alteration of the corresponding genes. For production of an adaptive enzyme, there is supposedly (6, 7) a need for energy, for building materials (N sources, internal or external), for the specific substrate, and for the corresponding gene, in phage-infected bacteria, the gene would be the missing (or incapacitated) ingredient. According to this hypothesis of 'genetic parasitism', we should consider cases of lysogenicity as examples of 'genetic symbiosis' between phage and bacterium.

It is important to remember that neither these experiments nor any chemical results tell us anything as yet as to *how* the infecting phage acts in impressing specificity on the newly formed

¹ Atlantic City, N. J., April 20, 1950.

³ Present address: Department of Bacteriology, University of Illinois, Urbana, Illinois.

material. Actually, we have as yet no idea as to what chemical fraction of the phage (or of any other biological material) is responsible for specificity, nor as to what role, if any, the nucleic acid or protein fractions of a so-called nucleoprotein may play in replication of specificity.

The 'activity cycle' approach attacks the problem of reproduction at the biological level, by tracing the specific virus material through its ability to reproduce. Reproduction takes place in the latent period between infection and lysis, at the end of which several hundred new active particles may be produced. Premature disruption of infected bacteria (8, 9) reveals, first, an 'eclipse' period, during which no active virus is recoverable, followed by the appearance and gradual increase of virus activity in the second half of the latent period. The early eclipse (an apparently general occurrence in virus infections) suggests a reorganization of the virus material into a non-infectious form.⁴ What goes on during the eclipse period? Genetic studies throw some light here. As has been described in this symposium, mixed infection with phage particles of two related types differing by at least two characteristics (such differences can originate by mutation) gives rise to recombinant types in rather precise proportions (11, 12). The fact that recombinant types are present with similar frequency in the final yield and among the very first active particles that appear inside the bacterium around the middle of the latent period (9) indicates that, whatever the reorganization that makes recombination possible, it must take place as early as the formation of the first active virus or earlier. The recombinants of reciprocal types formed within individual bacteria are not present in equal or even correlated numbers (9, 13), this suggests that they do not result from reciprocal exchanges of parts among pairs of mature particles. Moreover, the particles of each recombinant type in individual bacteria are distributed at random, without any sign of 'clonal' arrangement. This suggests that recombination occurs

at a stage in production of virus after which that virus does not act any more as a model for further virus production.

I have recently obtained very different results by studying the distribution of spontaneous phage 'mutants' (rather than recombinants) produced in individual bacteria. This distribution, based on 95 bacteria-liberating mutants of phage T2 out of over 5000 examined, is definitely clonal and quite similar to the one expected if each new mutant gave rise by successive reduplications to a 'clone' of mutant elements. We know that in phage spontaneous mutations occur only during reproduction (14), probably during actual replication of genetic material. The above result suggests then that there is a phase of logarithmic reduplication of phage material, during which mutations occur but recombinants are not yet formed. Recombinants, then, are probably formed after reproduction of phage material but not after the formation of active particles. A possible interpretation is that individual specific units or groups of units composing the phage reproduce severally and that the new materials are then taken up by an assembly mechanism (working after reproduction or more likely concurrently with it) that organizes them into mature particles (15), recombination would simply express the chances for the alternative forms of a given genetic unit to be brought together with those of another. This picture requires, of course, confirmation by other evidence before it can be considered as anything more than a working hypothesis. One of its features, which I find particularly appealing, is that it considers the virus, as we know it in its morphologically complex extracellular state, as a sort of resting stage, which appears to be the terminal form of a complex process of reproduction. In studying phage production, we would, then, be dealing at some point directly with events taking place beyond the geometrical and chemical limitations placed by such a highly organized structure as an active phage particle. This strengthens my confidence that phage workers—with different tools but with shared enthusiasm—are all prying into the level itself at which the mystery of biological replication is enacted.

⁴ Possibly, inside lysogenic bacteria the phage is always in such form but for the occasional outbursts of phage liberation (10).

BIOCHEMICAL STUDIES ON MULTIPLICATION OF BACTERIAL VIRUSES¹

SEYMOUR S COHEN

From the Department of Pediatrics, Children's Hospital of Philadelphia, and the Department of Physiological Chemistry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

THE PURPOSE of this paper is to summarize those chemical studies on virus-infected bacteria which suggest the mode of multiplication of the bacterial viruses.² In this survey we shall not consider the important subjects of adsorption or lysis but primarily those major synthetic steps culminating in virus formation. These steps have been studied in a system whose technical attributes permit controllable virus infection of essentially all the bacterial host cells. Various aspects of the biology and manipulation of the system have been summarized in numerous reviews.

We shall deal in the main with some even-numbered T phages, T2, T4, and T6, which parasitize *E. coli*. These tadpole shaped viruses are about 120 m μ long and 80 m μ across and contain large amounts of nucleoprotein organized within the head, which is bounded by a distinct membrane. T2 and T6, for instance, contain about 40 per cent of desoxyribose nucleic acid (DNA), and at least 55 per cent protein (1-4). There is some discussion going on as to whether these 2 components might not represent the entire phage. The absolute purity of various types of purified preparations creates a rather difficult problem.

We have recently shown (5) that when ultracentrifugally purified preparations of these viruses are found to contain phosphorus (P) other than DNA-P, these preparations still contain bac-

terial debris. This debris then has been shown to contain most, if not all, of the non-DNA-P. In any case well over 95 per cent of the total P is DNA-P, in contrast to the host which may contain three to five times as much ribose nucleic acid (RNA) as DNA.

When the host cells of a growing culture are infected, the cells stop multiplying. In Warburg respirometers, the increase in the rate of O₂ consumption observed in the growing culture is stopped by virus infection but respiration continues unchanged (2). This is true also on treatment of cells with virus inactivated by ultraviolet light. This simple experiment indicates that the production of respiratory enzymes has been halted, however, energy production appears to be maintained by the host's enzymes, a view which is strengthened by the findings that the RQ of the infected cell is unchanged as is the ratio of carbon burned to that assimilated. Of course maintenance of respiration alone is no measure of the maintenance and development of utilizable energy, evidence on the quantity of assimilation is essential to this conclusion.

In addition it is found that N and P are assimilated, and that nucleoprotein is being made in considerable amounts (3, 6). However, although the P entering normal cells passes through intermediates and is deposited in large measure in RNA and DNA, the P entering infected cells ends essentially in DNA, the nucleic acid characteristic of virus. This P appears there in such amounts and at a rate which suggests that it is the same P which in the uninfected cell would have appeared in the two nucleic acids. That is, there appears to be a basic shunt at some stage of P utilization which throws this P into the path of DNA synthesis. Much of this P may be isolated later in virus.

This shunt in P utilization has seemed to us to be crucial to the economy of the infected cell in establishing the parasitic relations which are being described. In line with our interest in the

¹ This research was supported in part by a grant from The Commonwealth Fund, and in part by Office of Naval Research Contract N6 on-188, Task Order 1, NR 135-055.

² Some recent essays on virus multiplication have implied a rigorous separation of the levels of organization being examined by chemical and biological investigations as well as of the deductions possible from the two lines of work. The inacceptability of this viewpoint in general is especially manifest in the field of virology where it is the task of the biochemist to study genetic duplication at molecular and intermolecular levels.

precise site of the shunt, we have recently studied and demonstrated an enzymatic pathway for ribose phosphate formation from 6-phosphogluconic acid in cell-free systems (7)

It has been shown by means of radioactive P in several laboratories (3, 8, 9) that about 75 to 80 per cent of the P appearing in virus comes from the medium after infection. It has not yet been resolved whether the extra 20 to 25 per cent comes from low molecular phosphorus-containing intermediates or from host DNA.

In the course of these studies we have shown (3, 8) that the P appearing in DNA does not pass

shown later, is increasing, we can say that above initial virus cell ratios of 4, the rate of virus DNA synthesis is independent of the numbers of intracellular virus particles.

It has also been shown that the maximal rate of virus DNA synthesis in infected cells was the same whether the infecting virus was T2r, T4r, or T6r (10). The amount of the DNA produced approaches the amount of DNA found in the virus liberated from these cells (10).

At this point, some conclusions may be formulated. The host bacterium weighs about 10^{-12} gm, the virus 10^{-16} gm. In an infected cell the respira-

Fig. 1. A comparison of synthesis of DNA in cells multiply infected with T6r+ or T6r virus (10)

through an appreciable fraction of RNA, i.e. RNA is not a precursor of DNA in this system. Indeed the bulk of the original nucleic acid of the host, the RNA, appears to be quite inert under conditions of infection. Recent unpublished experiments of Hershey *et al* indicate that once the virus DNA is formed, its P also does not have an appreciable turnover.

The course of DNA synthesis in *E. coli* infected with each of 2 related virus strains, e.g. T6r+ and T6r, is presented in figure 1 (10). It can be noted that there is a lag of about 10 minutes before DNA synthesis begins, that synthesis in each case falls on the same curve, and that this synthesis occurs at a constant rate for most of the course of synthesis. Since intracellular virus, as will be

tion and quantitative assimilation pattern of P and C resembles the capabilities of the enzymes of the host. Furthermore the amounts of material synthesized imply the continued activity of these enzymes in the infected cell. Nevertheless the compounds produced are built in the main into virus, and at rates independent of the numbers of virus particles and, to a certain extent at least, independent of the kind of virus. We conclude from these considerations that the complex virus polymers are being synthesized by host enzymes and, in addition we note that these rates of synthesis of virus substances are constant, unlike most instances of bacterial growth and division which are exponential processes.

Since this suggested that intracellular virus

formation was also a nonexponential process, it was important to study the correlation of DNA synthesis and the formation of complete virus. After Dr Doermann worked out the method to be described in his paper, we compared the formation of DNA and intracellular T4 virus in the same infected cells in joint experiments (11). In figure 2, it can be seen that the rates of synthesis were essentially similar, i. e. that intact virus formation is also an additive and not an exponential process. However, it should be noted that DNA synthesis does not finish off the virus—there is an additional step involving several minutes to be explored.

Protein is synthesized from the very beginning of infection (fig. 3). There is considerable synthesis, again at a constant rate, and independent of the genetic character of the virus (10). There are many important difficult problems to be solved about this protein, one of which is the question of whether it is all virus protein. It is suggestive but not conclusive that bacterial respiratory systems are not being synthesized and Monod and Wollman (12) have shown that certain adaptive enzymes cannot be synthesized in infected cells. Fowler and Cohen (13, 14) have shown the dependence of virus synthesis on amino acids and other substances in the medium by many methods and these data as well as the serological specificity of the phages imply *de novo* synthesis of phage protein. These questions are also being explored by Kozloff *et al.* (15) who have shown with isotopic N that 92 per cent of virus protein N comes from the medium after infection and not from the host N existing prior to infection.

In line with the demonstration of nutritional requirements for virus synthesis, we have shown that specific amino-acid antimetabolites such as 5-methyl tryptophan among others can reversibly block virus formation (16, 17, 13). Thus a knowledge of the synthetic steps in virus formation leads to a rational chemotherapy of virus infections (11). It is not intended to minimize the technical problems of obtaining such data and developing a chemotherapy for virus diseases of man and other forms. However, it must be emphasized that a methodology for a rational chemotherapy of virus infections does exist.

From the ultraviolet absorption spectra of infected cells, it is possible to get a picture of purine and pyrimidine formation (18). The spectra for DNA, the virus, and the bacterial host, all have marked peaks at 2600 Å due to the purine

and pyrimidine absorption. If we follow the increment at this wave length in suspensions of infected cells and multiply by the density, con-

Fig. 2 THE SYNTHESIS OF DNA and intracellular T4r during the latent period of virus multiplication (11)

Fig. 3 A COMPARISON OF PROTEIN AND DNA synthesis in cells multiply infected with T4r⁺ or T4r⁻ virus (10)

centration factor established on DNA, we can convert this increment to DNA. If we simultaneously estimate protein-bound DNA chemically, the curves are found to be quite parallel but not coincident. These data would seem to imply that purines and pyrimidines are synthe-

slightly greater than the density increment in normally infected cells. The spectrum of the increment maintained a peak at 2600 Å and this absorption was presumably due to synthesis of purines and pyrimidines. Thus there was a total inhibition for a definite period at the level of DNA polymer synthesis, but not apparently of purine and pyrimidine. We have measured the appearance of intracellular virus by Doeimann's method in this system and it was found that the appearance of intracellular virus was displaced as was the inception of DNA synthesis, i.e. the appearance of one particle per cell coincides closely with the beginning of DNA synthesis in this system. Thus a total inhibition of DNA synthesis and complete virus formation occurred for a limited reshuffling period despite the presence within the infected cell of a full complement of active genetic units. Therefore we have concluded that if DNA synthesis is essential to genetic duplication, the reproduction of genetic units requires the interdependent activity of all the undamaged genetic units. The alternative is that an increase in DNA has nothing to do with the reproduction of genetic units (18). Clearly this system may provide a critical test of the bare chemical requisites of genetic continuity.

In a study of P uptake in this mutual reactivation system we have found that there is no binding of P to protein before DNA is formed, i.e. there is no synthesis of protein-bound nucleic

acid at all. As can be observed in figure 5, inorganic P was converted to organic P and these organic phosphates, possibly some early stage of DNA precursors, accumulated within the cell in an acid soluble form. Obviously the precise nature of the small amounts of these phosphates which accumulate in this system is an important problem. Although there was no net increase in protein-bound P or nucleic acid, protein synthesis proceeded nevertheless, i.e. there was an increase in trichloroacetic-acid precipitable nitrogen almost as fast as in the normally infected cell. In another approach to the same problem, Raff and Cohen have shown that the removal of tryptophan from the medium in this system prior to DNA synthesis was even faster than in normally infected cells (23) (fig. 6). We do not yet know whether this system is synthesizing virus or bacterial protein under these conditions.

Thus while normally infected cells permit a study of DNA synthesis uncomplicated by RNA synthesis, cells infected with irradiated virus may under special conditions permit the study of protein synthesis uncomplicated by any nucleic acid synthesis as well as the study of interrupted stages of DNA synthesis. Indeed the bacterial virus systems are important biochemical tools in the study of protein and nucleic acid synthesis no less than their importance in the study of the basic problem of how a virus multiplies.

INTRACELLULAR PHAGE GROWTH AS STUDIED BY PREMATURE LYSIS¹

A H DOERMANN²

From the Department of Genetics, Carnegie Institution of Washington, Cold Spring Harbor, New York, and the Biology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

EVER since the beginnings of research on the reproduction of bacteriophage, one of the most imposing difficulties has been that the infected host cell presents a closed door to the investigator. At the beginning of the growth cycle, one or more virus particles become attached to the bacterium and after a certain length of time the cell bursts, yielding anywhere from a few to a thousand new phage particles. The purpose of this symposium is to summarize what is known concerning the events transpiring behind that closed door. From Dr. Cohen's discussion it is seen that considerable information is available concerning the chemical changes which occur within the infected cell, and Latarjet's (1) experiments with x-ray survival of phage inside infected bacteria have given some quantitative information about the intracellular picture. Yet in the absence of a method for titrating intracellular bacteriophage, it has been difficult to translate these results into a biological framework. My purpose in this discussion will be twofold: first, it will be to describe briefly the methods which have now been developed for estimating intracellular virus and to summarize the results which have been obtained; second it will be to present genetic data, coupled in part with intracellular assays. Similarly to the results presented by Dr. Cohen, these results will force us to the conclusion that the infecting particle must undergo some alteration prior to reproduction, and that its multiplication is not accomplished by serial fissions of the whole infecting virus particle.

With reference to the first objective, we have devised two methods of titrating the intracellular

bacteriophage population. Either of these methods gives satisfactory results under the proper conditions. Due to lack of time it is impossible to describe the methods in all particulars, nor is it possible to give all the details of evidence for accepting the results which have been obtained with them. They will, however, be briefly described and compared. Both methods depend on disrupting the infected bacterium, and since we know of no methods that will do this instantaneously without inactivating the virus, they both depend also on arresting phage reproduction during a period in which the cells are broken down. The first technique, which will be referred to as the cyanide-lysis method, relies for stopping phage growth on the introduction of 0.01 M cyanide. In the presence of this inhibiting agent, the bacteria are opened up by adding a large excess of a second phage type. In our experiments T6 has been used exclusively for this purpose, and the adsorption of large numbers of this second phage causes lysis of the cells (2). In order to assay the phage whose growth we are studying in the presence of a large excess of the lysing agent T6, it is necessary to plate against the bacterial strain B/6 which is specifically and totally resistant to T6, while all the other phages which we have used form plaques when plated against B/6.

The second method, which will be called the sonic method, was devised in cooperation with Dr. T. F. Anderson in his laboratory at the Johnson Foundation of the University of Pennsylvania. This method, by contrast with the other, does not depend on cyanide to stop virus multiplication, but depends on reducing the temperature to 5° or lower during a 5-minute interval in which the infected cells are exposed to intense sonic vibrations. This treatment disrupts some 90 to 95 per cent of the infected bacteria. This method is unfortunately applicable only to those phages which show moderate resistance to sonic energy. Among the members of the T series these are T3, T7, and possibly T1 (3).

The first results which I would like to discuss

¹Work at Oak Ridge done under contract No. W-7405-Eng-26 for the Atomic Energy Commission.

²The author is indebted to Dr. M. Demerec and the staff of the Department of Genetics, Carnegie Institution of Washington, for providing facilities and a stimulating environment for these experiments, and to the staff of the Biology Division, Oak Ridge National Laboratory, for material and intellectual aid in preparation of the manuscript.

are seen in figure 1, and are from an experiment done with Dr Anderson. Its purpose was to compare the results obtained with the two methods described above. Separate aliquots of a T3-infected bacterial suspension were treated simultaneously with the two methods. From a third untreated aliquot control lysis was determined. Attention should be directed to several aspects of the results shown in the figure. It is seen that, in

to 95 per cent of the cells are disrupted. From the figure it can be seen that the titer of plaque-forming particles per ml in the early stages with sonic treatment is between 5 and 10 per cent of the infected bacterial titer. As the yield of phage per cell approaches one, the small fraction becomes negligible.

The agreement in the ascending portions of the curves can be taken to indicate that both meth-

Fig 1 COMPARISON of cyanide-lysis procedure with sonic method for estimation of intracellular bacteriophage

the ascending portions of the curves, there is close agreement in the results from the sonic disruption treatment and the cyanide-lysis treatment. The only discrepancy is found in the earliest points, where both curves fall far below the control lysis curve. This difference is due to a difficulty in technique, as is seen from the following considerations. Any infected, unlysed cell will make one plaque. In the case of the cyanide and T6-treated aliquots very nearly 100 per cent of the cells are broken down by the treatment. With the sonic treatment, however, only some 90

ods give about the same intracellular phage estimate. It is furthermore evident that the two procedures are independent of each other since separate techniques of disruption have been employed and since different mechanisms were used to stop phage growth. The agreement between the results, therefore, constitutes convincing evidence for accepting these methods as adequate for titrating the intracellular bacteriophage population.

Results very similar to those obtained with T3 were found when the intracellular development

of T4 was followed by the cyanide lysis technique. The curves were similar in shape, but spread out over the longer latent period of T1. Again none of the original infecting particles were recovered, even when the multiplicity of infection was in excess of 5 phage particles per cell.

The question which naturally follows here is how the results of intracellular titrations fit with the intracellular chemistry studies which were presented by Dr. Cohen. He has already answered this question, and I wish only to recall to your attention the striking parallel in the accumulation of newly synthesized deoxyribose nucleic acid in the cell and the subsequent increase in mature phage particles.

A little more detail may be added to the results of the intracellular titrations by investigating the

whole cultures are plated out. When this was done with bacteria infected with 5 to 10 T2H particles per cell, the results shown in figure 2 were obtained. The average yield of phage per cell in the 5 experiments ranged from 30 to 60, and the individual bursts were plotted as percentage of the average in a given experiment. The average yields per cell from those allowed to lyse normally was around 300. It is seen that there is a wide range, percentage-wise, in the cells which were disrupted ahead of their normal lysis time, indicating that the cells are not uniform in the time at which the first phage particle appears in them. The spread found is similar to that obtained from normally lysing T1-infected cells by Delbrück (4) and T2H-infected cells by Hershey and Rotman (5).

Fig. 2. DISTRIBUTION of intracellular bacteriophage particles among individual bacteria as found by cyanide-lysis procedure.

phage present in individual bacterial cells. Since the experiments of Delbrück (4) published five years ago it has been known that there is a wide range in the yield from individual cells which lyse normally. It seemed worthwhile, therefore, to adapt the cyanide-lysis procedure to titrating the phage within single bacterial cells. The technique depends on diluting the infected bacteria to a point where single drops will have a small probability of containing an infected bacterium. From this highly diluted culture single drops are dispensed into many individual tubes at some stage before one wants to induce lysis. The majority of the cultures which contain an infected bacterium under these conditions will contain only one. The cultures are incubated at the desired growth temperature until the time of lysis induction. They are then placed in an ice bath, and cyanide and T6 are added quickly. After a suitable period for lysis induction, the

TABLE 1. OCCURRENCE OF GENETIC RECOMBINANTS IN THE CROSS T2H_{r1} x T2H_h DURING THE LATENT PERIOD

EXPER. NO.	TIME OF CYANIDE TREATMENT	NO. PHAGE PER CELL	TOTAL RECOMBINANTS OBSERVED		PERCENT RECOMBINANTS
			<i>rh</i>	<i>r⁺h⁺</i>	
1	20	23	6	4	2.0
2	20	60	49	48	2.2
1	25	36	2	6	1.6
3	27	67	45	36	2.4
2	29	102	18	16	2.3
1	30	113	11	8	3.0
1	Control burst	288	31	16	3.0
2	Control burst	516	72	59	3.5
3	Control burst	365	15	12	2.3

The number of bursts obtained in these experiments is slightly lower than would be expected on the basis of the number of infected

bacteria known to be present. This is to be expected, however, if a few of the infected cells do not yet contain any mature phage particles at the time of induced lysis. The fair agreement between the number of bursts and the expected number indicates clearly that the treatment used for inducing lysis is obtaining phage from all of the cells and not merely from a few which might be sensitive to the lytic procedure.

From the results so far presented, the major conclusion appears to be that the infecting particles, whether they be one or many per cell, are not recoverable as such, and that they have undergone some change that prevents them from forming a plaque when the cell is disrupted. This is in agreement with the much earlier experiments of Delbrück and Luria (6) in which they infected cells simultaneously with T1 and T2 (α and γ). Under these conditions, T2 completely suppresses the multiplication of T1. Furthermore, when the yields from these cells were examined, not even the infecting particles of T1 were found.

I would like now to turn to some of the genetic experiments which shed a little more light on the problem of intracellular reproduction of bacterial viruses. From the data so far presented one might still believe that the intracellular multiplication is accomplished through binary fission of the infecting virus particle. The non-exponential nature of the curves of intracellular virus increase could be explained by assuming some limiting synthetic reaction, and the early disappearance of the infecting particles might be due to a temporarily irreversible attachment to the bacterial components. The genetic experiments, however, furnish convincing evidence against the hypothesis of binary fission.

The basic experiments in this regard have been done by Hershey and Rotman (5). They infected bacteria simultaneously with two types of T2H which differed from each other in two differentiable hereditary loci. The yield from such bacteria consisted of the two parental genotypes, but in addition, two new types which were identified as the other two combinations of the genetic markers. When the yields from individual bacteria

were analyzed, the two genetic recombinant types were found in equal proportion and furthermore the recombinants occurred in statistically the same proportion in each of the individual cells. In other words, there were no yields containing unusually large clones of the recombinant types. Even the mere fact that recombination of genetic material does occur would be difficult to explain on a binary fission hypothesis. However, assuming such a hypothesis, and admitting the possibility that whole phage particles could transfer genetic properties, one must still account for the non-clonal distribution of the recombinants. The amendment would, therefore, have to be added to the hypothesis that recombination occurs only in the later stages of multiplication.

We have attempted to answer the question whether any of the first completed phage particles may be of the recombinant types. A cross was made after the technique of Hershey and Rotman (5), but instead of allowing the latent period to go to completion, it was interrupted at several points with the cyanide-lysis technique. The cross used was one of those described by Hershey and Rotman, namely $T2H_{r13} \times T2H_h$. When the cells are allowed to lyse normally, this cross gives 2 to 3 per cent recombinants. This particular cross with low recombination was selected in preference to high recombination crosses for the following reason: on the binary fission hypothesis the absence of clones would more definitely preclude the early occurrence of recombinants than in cases where a high percentage of recombination occurs.

The results of the experiment (table 1) show that even when there is a small number of phage particles per cell, the percentage of recombinants is about as high as is found when cells are allowed to lyse normally. On the hypothesis of binary fission, these early recombinants would necessarily grow into clones. Hershey and Rotman's evidence is unequivocal that no clones are found. One must therefore conclude that the phages of the T-even series do not multiply by binary fission, and further that the first completed phage particles are not themselves the parents of those viruses which appear later within the same cell.

nuclear

Instruments for CIVIL DEFENSE

IN order to meet the specialized needs of Civil Defense organization, NUCLEAR has developed specialized instruments for civilian protection. From a pocket monitor to complete central station continuous radioactivity recording systems, NUCLEAR instrumentation offers reliable, efficient units for Civil Defense use.

Briefly described below are three of the most recently perfected NUCLEAR instruments for Civil Defense. Complete details on these and other NUCLEAR instruments will be furnished promptly upon request.

nuclear "CIVION" (Model 2383)—Compact High-Level Monitor

- **SMALL**—only 2" x 3" x 6 1/4"
- **LIGHT**—weighs 21 ounces
- **WATERTIGHT**—tough plastic case can be immersed in water without damage
- **READING RANGE** from 0.25 r/hr to 500 r/hr
- **DETECTS** gamma and strong beta radiation
- **ONE CONTROL** is "ON OFF" switch in convenient thumb operating position
- **ILLUMINATED METER** for night use
- **LONG LIFE** from batteries in excess of 100 hours continuous
- **NO ZERO SET** required except when replacing batteries
- **BATTERIES** quickly replaceable without tools
- **METER** damped for stability, clearly marked 2" scale under magnifying lens window
- **ALL-PLASTIC ION CHAMBER** for true roentgen reading within F C D A tolerance

nuclear (Model 2610A) BETA-GAMMA MONITOR

- **APPROVED** by F C D A for low level monitoring
- **LIGHTWEIGHT**—10" x 4 3/4" x 5 3/4" With batteries, weighs 9 1/2 lbs
- **WATERTIGHT** instrument case and probe
- **ONE-HAND** operation
- **SHIELDED PROBE** for beta and gamma discrimination
- **PLUG-IN GEIGER TUBE** requires no soldering
- **RANGES:** 0.2, 2, 20 milliroentgens per hour full scale
- **AUDIO** and **VISUAL** radiation indications
- **RADIOACTIVE CALIBRATION SOURCE** mounted on instrument

nuclear (Model 2584) GAMMA SURVEY METER

(AN/PDR T1 Type as recommended by F C D A)

NUCLEAR Model 2584 is a MODERN development of the wide range, low level AN/PDR T1 Meter, with these improvements:

- **DIAL LIGHT** switch more rugged, protected against turning on accidentally
- **CASE** is all cast aluminum in two parts for more stable operation
- **WATERTIGHT**, yet can be arranged for opening quickly without tools
- **PUSH-BUTTON** zero check allows check without changing range setting
- **CIRCUIT** redesigned for greater simplicity, equal or better dependability, easier access

RANGES: 0.5; 0.50; 0.500; 0.5,000; 0.50,000 mr/hr

POWER SUPPLY self contained batteries, quickly accessible for replacement.

in 1960, you'll be glad you used **GOLD SEAL SLIDES and COVER GLASSES**

Choice of leading pathologists and
anatomists because . . .

GOLD SEAL MICRO SLIDES

are made of a special, hard, non-corrosive glass—almost colorless, and uniform in thickness, length and width

They are factory inspected and selected to eliminate striae, bubbles, scratches and other imperfections. Edges are beveled, ground and polished. Slides are washed before packing.

GOLD SEAL COVER GLASSES

are made of a special domestic glass of extreme hardness, containing a minimum of alkali, non-corrosive and non-fogging

They are cut, selected, gauged and packed in our New York City workrooms by technicians trained in the accurate cutting, selection and gauging of cover glasses, and equipped with the best apparatus available for this purpose

MODEL 3C STIMULATOR

A GENERAL PURPOSE PHYSIOLOGICAL STIMULATOR

The accuracy and versatility of this square-wave stimulator allow its use without monitoring in a wide variety of nerve, muscle and cortical stimulation problems. Frequency, duration and voltage of the stimulus are independently variable and each is accurate to better than 5%. The stimulus has a variable time delay from the cathode-ray synchronizing pulse. This stimulator gives single, groups or continuously repetitive pulses, and in combination with a similar stimulator, gives two pulses whose separation, duration and voltage are all independently variable.

Stimulating electrodes of various types are available.

Grass Instrument Company also manufactures

Preamplifiers — used extensively in nerve-muscle physiology in conjunction with commercial cathode-ray oscilloscopes having some amplification,

Electroencephalographs — used clinically and in experimental neurophysiology and pharmacology,

Electrodes — scalp type for recording the EEG, Cortical electrodes for recording the EEG from exposed brain in animals and humans, and depth electrodes for stimulating, recording and injecting fluids into the depths of the brain.

Write us for full specifications on any of the above.

Prompt delivery on most items.

nuclear "PRECISION INSTRUMENTATION FOR NUCLEAR MEASUREMENTS"

FOR
diabetic control
AS INDIVIDUAL AS A FINGERPRINT

The administration of Protamine Zinc Insulin is a cornerstone in the treatment of practically all diabetics because of its slow but prolonged effect. Unmodified Insulin is employed either as a supplement or as an alternative whenever a quick and short but powerful action is required. In emergencies and during diabetic complications, the rapidly acting preparation is especially indicated.

Mixtures of the two preparations provide an intermediate "adjustable" effect. No single Insulin preparation is indicated for all diabetics. The treatment of each diabetic is an individual problem—as individual as a fingerprint.

Complete literature and diet forms for the treatment of diabetes are available from your Lilly Medical Service Representative or will be forwarded to members of the medical profession upon request.

Optimum frequencies for sonic disintegration of paramecia EUGENE ACKERMAN (introduced by J A E EISTER) *Johnson Fndn, Univ of Pennsylvania, Philadelphia*

The disintegration of *Paramecium caudatum* by intense sound waves of audible frequencies was studied. Sonic fields were generated by a magnetically driven, steel diaphragm which formed the bottom of a cup which contained the aqueous suspension being treated. Frequency of vibration, time of exposure, and concentration of cells before and after treatment were measured. Sonic velocities were measured with a calibrated phonograph cartridge in contact with the driving magnet. The ratio of the concentration of the survivors, N , at a time t , to the original concentration N_0 , obeyed the relationship $\ln(N/N_0) = Kvt$ where V represents the peak velocity of the water. The rate factor, K , is independent of the frequency except in the range 1,100 to 1,300 cycles/sec, where K rises to a maximum at 1200 cycles/sec of 6 times its value outside this range. Different maxima were found for 3 other *Paramecium* species, the optimum frequencies increasing as the size decreased. These results were checked with mixtures of 2 species. Vibrational modes of cells are readily excited by stresses in the water due to cavitation. Spherical cells in this size range would have appropriate resonant frequencies if they had interfacial tensions of about 3 dynes/cm or a cortex with the rigidity of a fibrin gel. *Trichomonas foetus* and mammalian erythrocytes, which are much smaller, gave constant K values throughout this range.

Adrenalectomy and proteinuria in the rat T

ADDIS,¹ J MARMORSTON,* H GOODMAN* AND A SELLERS * *Inst for Med Research, Cedars of Lebanon Hospital, Los Angeles, Calif*

The normal rat responds to the intraperitoneal injection of 4 units of hog renin diluted in 4 cc of normal saline solution by an intense proteinuria, averaging 31.7 mg of protein/hour. Protein excretion drops to 1 mg/hour in response to the same dose of renin in the bilaterally adrenalectomized, salt-maintained animal. Desoxy corticosterone acetate (0.5 mg daily, subcutaneously), aqueous

adrenal cortex extract (2 cc daily, intraperitoneally), and 11-dehydro-17-hydroxycorticosterone acetate (compound E) (10 mg daily, subcutaneously) administered to the salt-maintained, adrenalectomized rat restores its ability to respond to intraperitoneal renin injections by proteinuria as massive as that found in the intact normal animal. The intraperitoneal injection of 2 or 3 grams of human serum albumin (6% solution in normal saline) produces an intense transient proteinuria in the rat averaging 510 mg for the 18 hours following the injection. Following bilateral adrenalectomy, the protein excretion after human serum albumin injection is reduced to 75 mg for the 18-hour period after the albumin injection. The spontaneous proteinuria found in the normal male rat is significantly reduced in the adrenalectomized, salt-maintained animals.

Sex difference in proteinuria of normal rats T

ADDIS,¹ J MARMORSTON,* H GOODMAN* AND A SELLERS * *Inst for Med Research, Cedars of Lebanon Hospital, Los Angeles, Calif*

The rate of spontaneous protein excretion in normal male and female rats is identical until 50-60 days of age (approximately the age of puberty), at which time, the rate of protein excretion in the male rises sharply several fold above that found in the female. This increased rate of protein excretion in the normal male rat persists until at least 200 days of age. Observations were not made after this age. The rate of spontaneous protein excretion in castrate male rats is not essentially different from that found in the female at all ages from 30-200 days. In order to determine whether the increased protein found in the urine of male rats had its origin in the kidney or in the accessory sex glands, normal male and female rats of 120-130 days of age were injected with 5 cc of normal saline solution subcutaneously. At the end of one hour, the base of the distended bladder was clamped and the urine withdrawn by puncture through an avascular portion. The protein content of the bladder and voided urines are essentially the same. It is concluded that the protein excreted by the normal male and female rat comes directly from the kidney, il-

¹ Deceased.

¹ Deceased.

though the bladder is not entirely eliminated as a minor source of some excreted protein

Labile factor of prothrombin conversion its consumption in normal and abnormal blood coagulation BENJAMIN ALEXANDER, GRETA LANDWEHR AND ROBERT GOLDSTEIN (introduced by HERRMAN L BLUMGART) *Med Research Labs, Beth Israel Hospital, and the Dept of Medicine, Harvard Med School, Boston, Mass*

Rapid prothrombin conversion to thrombin requires a plasma component called "Labile Factor" (L F). Whereas its concentration in plasma is known its level in serum is obscure. Such information is necessary to elucidate its role in coagulation and to permit precise determination of serum prothrombin by measuring its prothrombin time. Prothrombin was determined by a modified one-stage procedure in which the material was diluted with fresh plasma rendered prothrombin-free by BaSO₄. Prothrombin times were interpolated on standardization curves obtained on normal plasma similarly diluted. L F was measured by its ability to rectify the retarded prothrombin conversion of aged plasma devoid of the factor. Plasma and sera were first adsorbed by BaSO₄ to remove prothrombin and spea. They were then added (whole or diluted) to stored pooled plasma (1-4) and the prothrombin times of the mixtures were determined. Normal serum, separated one hour after coagulation, contains much less L F than plasma. Accelerating coagulation by thromboplastin supplements reduces serum L F even further. Conversely, hemophilic and thrombocytopenic sera contain large amounts of L F. Similarly, dicumarol hypoprothrombinemic blood, with or without thromboplastin supplements, yields sera rich in L F. Thus Labile Factor is consumed in relation to the amount and velocity of prothrombin conversion, suggesting its role as reagent rather than catalyst. The significance of these observations in determining serum prothrombin and prothrombin consumption are discussed. Also, the relation between L F and prothrombin-converting-accessory factors reported by others are reviewed.

Influence of diaphragm on portal blood flow and venous return ROBERT S ALEXANDER *Dept of Physiology, Western Reserve Univ School of Medicine, Cleveland, Ohio*

Changes in the dynamics of portal blood flow associated with contraction of the diaphragm have been studied in anesthetized dogs by means of optical manometers and direct measurements of blood flow. Contraction of the diaphragm produced by phrenic nerve stimulation results in a rise in effective portal pressure in spite of a reduction in portal inflow from the mesenteric bed.

This is dependent upon an increase in resistance to blood flow in the mesenteric circuit and a proportionately greater increase in resistance to hepatic blood flow. These resistance changes are interpreted as being the result of mechanical compression of abdominal structures by diaphragmatic contraction. In addition, phasic changes in blood flow associated with diaphragmatic contraction suggest a 'milking' action of the diaphragm upon the portal system. In confirmation of this, intermittent stimulation of the phrenic nerve at short intervals markedly increases portal blood flow in spite of the changes in resistance to arterial inflow. This increased blood flow is not dependent upon changes in intrathoracic pressure. Comparisons have been made between these observations and comparable observations made during the normal respiratory cycle. It is concluded that the action of the diaphragm in milking blood from the portal system is an important factor contributing to venous return to the right heart, especially with rapid rates of respiration.

Effect of spinal cord lesions on positive and negative conditioned reflexes in dogs WILLIAM F ALLEN *Dept of Anatomy, Univ of Oregon Med School, Portland*

This study represents the results of transections of the mid-thoracic pyramidal or extrapyramidal fibers on acquired auditory-hindleg conditioned reflexes. Transections of the lateral pyramidal tract produced but little effect on the ipsilateral positive conditioned reflex and none on the negative reflex. Hemisection of the cord eliminated the ipsilateral hindleg conditioned reflex for 1000 trials, but the positive conditioned stimulus finally elicited a walking reflex of the hindlegs that started with the normal leg. The positive conditioned reflex was abolished for both hindlegs by a lesion that hemisected the left side of the cord, cut the right lateral pyramidal tract and a median strip of the right ventral pyramidal tract, but left uninjured many of the right ventral and lateral reticulospinal fibers. In this dog the positive conditioned stimulus evoked movements of the forelegs which dragged the hindlegs on the floor. The negative conditioned stimulus prevented this response, but did not stop a slow clonic movement of the right hindleg that began and ended with a daily session of tests. Transection of both ventral reticulospinal tracts produced no effect on the positive conditioned reflex for either hindleg and slight effect on the negative conditioned reflex. Transection of the ventral reticulospinal tracts and many of the right lateral reticulospinal fibers did not effect the positive conditioned reflex for the right hindleg, but eliminated the right negative conditioned reflex in over 1000 trials. A like transection which included

a large proportion of the left lateral reticulospinal fibers together with the ventral reticulospinal tracts did not affect the left hindleg positive conditioned reflex, but the negative conditioned reflex required over 2000 tests before re-establishment occurred. It would therefore appear that the reticulospinal tracts are as essential for this negative conditioned reflex as the pyramidal tracts for this positive conditioned reflex.

Effect of daily exposures to 18,000 feet simulated altitude upon life cycle of the rat PAUL D. ALLTAND AND BENJAMIN HIGHMAN (introduced by HEINZ SPECHT) *Natl Insts of Health, Bethesda, Md*

Sprague Dawley rats were exposed to 18,000 feet 4 hours daily beginning at 14 days of age and terminating at 540 days or prior death. Seventy-two rats were killed for study at intervals between 37 and 540 days, while 20 males and 30 females were observed for longevity. In contrast to the findings observed in rats similarly exposed to 25,000 feet, they showed no significant reduction in longevity compared with controls. Nine of 20 male rats died during exposure period, but 7 lived 700-798 days, 7 of 30 females died during exposure, but 14 lived from 700-928 days and 1 survived (1026 days). Males gained less weight than controls during exposure, but females grew normally. Hematocrit values (78% in males, 70% in females) remained at high levels from 100-350 days of age and then they declined to approximately 67% at 540 days. The polycythemia rapidly disappeared after cessation of exposures. Pathologic changes attributable to altitude were rarely severe. Some exposed animals showed fatty degeneration and hemosiderosis of the liver and kidney. Such changes tended to be more severe in animals with pneumonia and were seen only occasionally in controls. A few exposed rats showed slight thickening of the valvular leaflets, but there were no cardiac vegetations, renal infarcts, or massive intestinal hemorrhages as previously reported (1949) in rats exposed to 25,000 feet. These findings indicate that the life cycle of rats is not significantly altered by discontinuous exposures to 18,000 feet.

Cortical representation and spinal pathways of visceral afferents V. E. AMASSIAN (introduced by T. C. RUCH) *Dept of Physiology and Biophysics, Univ of Washington School of Medicine, Seattle*

Afferents distributed with sympathetic nerves to the viscera are represented in the trunk region of the cortical sensory areas of the cat and monkey. Under pentobarbital, latencies of the initial surface positive wave from single shock stimulation of the splanchnic nerve in the cat were 9.5-12 and

8-10.5 msec for contralateral areas I and II. Ipsilateral responses of 12-14 msec latency were found in area II, where the responses were best seen. The spinal pathway for the early splanchnic response is in the posterior columns. The evidence is that section of the posterior column at C₁ abolishes the early response, while section of anterior and lateral columns leaves it unimpaired. A series of action potentials appears in the posterior columns on splanchnic stimulation, and antidromic stimulation of the posterior columns gives a series of similar latency in the splanchnic nerve. From the latency of the initial wave, the conduction velocity of the fastest splanchnic afferents, expressed as an average for the pathway below the medulla, is estimated at 45 metres/sec, corresponding to fibers of 7.5 μ or over. Many of these are derived from pacinian corpuscles. No evidence could be found that the rapidly-conducting, visceral afferents initiate the early cortical response through an interaction with somatic lumbar or intercostal afferents below the medulla. This may have implications in theories of the reference of visceral sensation. Recordings from the anterolateral regions of the spinal cord have confirmed the presence of another ascending pathway with properties differing from those of the posterior columns.

Proteins obtained by long-continued mild extraction of whole mammalian muscles WILLIAM R. AMBERSON, SYLVIA HIMMELFARB* AND CAROLYN M. STOUT *Dept of Physiology, Univ of Maryland School of Medicine, Baltimore*

In extension of work previously reported (*Federation Proc* 7 2, 1948, *J Biol Chem* 181 405, 1949), whole rabbit muscles have been repeatedly extracted for as long as 4 months by the use of 5% and 10% potassium pyrophosphate solutions, at 0 °C. In the present work the muscles have not been frozen before or during extraction. Individual extraction periods are usually 2 or 4 weeks. The various series of resulting protein solutions have been subjected to electrophoretic analysis, and the time course of extraction of the several components followed. The major components, A, C, and D, reappear in many successive extraction periods, with the C component (myosin) gradually forming a larger percentage of the total extracted protein. Mobilities are not markedly altered for many weeks. Total protein extracted may finally reach as much as 10% of the original wet weight. After the first week a new component, which we designate as C', appear in the electrophoretic patterns. Its mobility is intermediate between C and D. It becomes well developed on the descending limb, but is very small on the ascending limb. The sum of the areas of C and C' on the descending limb is nearly the same as that of the same com-

ponents on the ascending limb. In the presence of C' the form of the D elevation is also modified, on the descending limb. It appears that C' is in some way related to both C and D components, but its identity has not been established.

Factors affecting quantitative comparison of direct and indirect effects of x-rays on enzymes

RUBERT S. ANDERSON *Dept. of Physiology and Pharmacology, Univ. of South Dakota School of Medicine, Vermillion, and Marine Biological Lab., Woods Hole, Mass.*

It is not at present possible to state definitely the relative importance of direct and indirect ('activated water' reactions) X-ray effects in irradiated living tissue. However, since both must occur to some extent, it is desirable to learn more of their characteristics in systems which are simpler than living cells. A number of comparisons have appeared in the literature, particularly on viruses, but less data is available on proteins having the molecular sizes of enzymes. Pepsin has therefore been irradiated, both in solution and after drying, and the loss of enzymatic activity determined. The loss in solution can, as was reported earlier, be increased several-fold merely by warming the solution of the enzyme after the irradiation. Also, in the case of the dry enzyme, a previously unrecognized factor is of importance in the quantitative result. When the number of molecules of pepsin inactivated per ion pair formed is calculated, the value is somewhat larger for the direct effect than for the indirect effect. The exact ratio depends upon conditions. However, there is nothing approaching the difference of 4000 to 1 reported by Lea for tobacco mosaic virus. In a 20-25% pepsin solution a substantial fraction of the inactivation would be calculated as due to the indirect reaction. Additional data is needed, since this suggests that the indirect reaction cannot yet be eliminated as insignificant within the cell, especially if the sensitive entities are small.

Diencephalic mechanisms for facilitation and inhibition

GEORGE AUSTIN* AND HERBERT JASPER *Dept. of Neurology and Neurosurgery, McGill Univ., and Montreal Neurological Inst., Montreal, Canada*

Recent studies have shown facilitatory mechanisms existing in the diencephalon to be associated with important changes in the electrical activity of the cerebral cortex. Inhibitory mechanisms have also been reported to have been activated from structures in the diencephalon and rostral mesencephalon which cause changes in electrocortical activity. Relationships between motor facilitation or inhibition and the changes in electrocortical activity have remained obscure.

In the present experiments stimulation points from the septum to the red nucleus of the cat have been mapped for their effects upon a) cortical induced movements, b) electrically recorded spinal reflexes, and c) electrocorticograms. Results of these experiments to date have shown the most marked facilitation of cortically induced movements and spinal reflexes from stimulation of the habenulopeduncular complex. Facilitation has also been obtained from the red nucleus, tegmental fasciculus, posterior hypothalamus, subthalamus and from portions of the thalamic reticular system, antero-medial nucleus and ventralis lateralis. Stimulation points producing inhibition have been found in the septum, dorsal hypothalamic area, and caudate nucleus. We have been unable to demonstrate a constant relationship between cortical electrical responses to these stimuli and the effect upon cortically induced movements, most of the motor effects being apparently downstream rather than via the cortex, as controlled by cortical ablation.

Potentialiation of diuretic action of salyrgan by ammonium chloride

D. R. AXELROD,* J. N. CAPPS* AND R. F. PITTS *Dept. of Physiology, Syracuse Univ. College of Medicine, Syracuse, N. Y.*

It is well recognized that the prior administration of ammonium chloride potentiates the action of mercurial diuretics, and that this potentiation is synergistic rather than merely additive. It is possible that the increased efficacy of mercury under these conditions is due a) to increased acidity of the body fluids, i.e. to a reduction in plasma pH, b) to alteration of anion pattern of the body fluids, i.e. to an increase in the plasma concentration of chloride at the expense of bicarbonate, c) to an increase in the acidity of the urine, or d) to other unrecognized mechanisms. An analysis of the possible relationship of these factors to the potentiation of salyrgan-theophylline in the dog is being attempted in the following way. An acidosis produced by the administration of 10 gm. of ammonium chloride on the day preceding the experiment lowers plasma pH to about 7.30 and increases plasma chloride and depresses plasma bicarbonate by about 10 mEq/l. respectively. A synergistic increase in sodium and chloride excretion is demonstrable on administering 1 or 2 cc. of salyrgan-theophylline (40-80 mg. Hg). An acidosis induced by the inhalation of 7 per cent CO_2 in air accompanied by an equivalent or greater drop in plasma pH but with a slight increase rather than a decrease in plasma bicarbonate does not enhance the activity of the mercurial diuretic. It would appear from experiments to date that plasma acidity is not a significant factor. Further studies are in progress.

Ascorbic acid and ketosteroid cytochemistry in the rat's adrenal cortex following prolonged injections of epinephrine HABEEB BACCHUS (introduced by C E LEESE) *Dept of Physiology, George Washington Univ School of Medicine, Washington, D C*

In an attempt to elucidate the relationship of ascorbic acid to secretory activity in the adrenal cortex, adrenals of rats receiving two injections of epinephrine daily for 8 days and for 15 days were examined using histochemical techniques for the detection of ketosteroids and of ascorbic acid. The resistance phase of the General Adaptation Syndrome (observed after 16 injections of epinephrine) is characterized by considerable enlargement, and increased ketosteroid content of the fascicular zone. The glomerular zone is shown to be normal in size and in ketosteroid content. The exhaustion phase (seen after 26 injections of epinephrine) is characterized by maximum hypertrophy of the fascicular zone, with considerable depletion of ketosteroids from the fascicular and reticular zones. The alarm reaction has been shown in previous work to be characterized by depletion of ketosteroids from the fascicular and reticular zones of normal sizes. Ascorbic acid cytochemistry indicated that two 'cell types' exist in the normal cortex, one 'type' with ascorbic acid diffusely distributed in the cytoplasm, and the other 'type', with ascorbic acid aggregated peripherally in the cytoplasm. The alarm reaction is characterized by the preponderance of the latter 'type' of cells. The resistance phase is characterized by the normal distribution of the cell 'types', the cells being larger than normal. The exhaustion phase is characterized by the occurrence of considerably enlarged cells which exhibit decrease in ascorbic acid content. These shifts may have some significance in the secretory activity of the cells of the adrenal cortex.

Ketosteroid and ascorbic acid cytochemistry observed in the adrenal cortices of rats flooded with either sodium or potassium chloride, or given prolonged injections of DCA HABEEB BACCHUS (introduced by E C ALBRITTON) *Dept of Physiology, George Washington Univ School of Medicine, Washington, D C*

The relation of the glomerular zone of the rat's adrenal cortex to increased intake of sodium chloride and of potassium chloride was tested by ketosteroid and ascorbic acid cytochemical techniques. A progressive structural and functional atrophy of the glomerular zone was observed in rats supplied with 2.5% NaCl as the sole of fluid intake (sodium chloride 'flooding'), for 9, 15, and 30 days. Adrenals of control animals exhibited normal ketosteroid and ascorbic acid distributions. The appearance of the zone of NaCl flooded ani-

mals was similar to that of animals receiving daily injections of desoxycorticosterone acetate for 30 days. Progressive structural and functional hypertrophy of the glomerular zone was observed in animals flooded with 2.5% KCl for 9, 15 and 30 days. One hour after intraperitoneal injection of either 0.85% NaCl or 2.5% NaCl, no changes were observed in the glomerular zone, but the alarm reaction was observed in the inner zones, of the cortex. These findings indicate that a) possibly the glomerular zone and not the cortex as a whole, is involved in controlling the sodium potassium ratio in the body, and b) the glomerular zone is not a 'stress' zone.

Effects of varying dilutions of Ringer's solution on the blood capillary bed of the rat mesoappendix THEODORE BALOURDAS* AND ROBERT CHAMBERS *Dept of Biology, New York Univ, Washington Square College of Arts and Science, New York City*

An account of the method and the topography of the vessels has been published (CHAMBERS AND ZWEIFACH *Am J Anat* 75 173, 1944). The caecum is extruded through an incision in the abdomen of the rat and the mesoappendix gently spread over a glass ring and mounted for microscopic observation. The mesoappendix and the exposed viscus is kept moist by a constant drip of Ringer's solution containing 1% ash-free gelatin and kept at 38° C. The present experiments were performed as above, except that the constitution of the drip is varied for the purpose of noting the effect of changing the environment of the capillary bed. The exposed mesoappendix was first subject to a drip of normal Ringer-gelatin solution for 10-15 minutes. For the experimental study only those preparations were used which were normal under previously determined standards and which exhibited the usual threshold sensitivity of one part of a standard solution of epinephrine (1:1000) in 1 to 4 million Ringer's solution. The drip was then changed to $\frac{1}{2}$, $\frac{1}{4}$ or $\frac{1}{8}$ of normal and, after 10-15 minutes, the epinephrine sensitivity again tested. The sensitivity to epinephrine rose appreciably with time and with increasing dilution of the drip solution. Threshold sensitivity rose progressively from 1:20, 1:240 and 1:600 million. The most pronounced increase occurred when the dilution of the drip was $\frac{1}{8}$ of the Ringer's solution in which the epinephrine sensitivity rose in one case to the extreme value of 1:1200 million. At the end of the experiments of 1 to 2 hours, the drip solution was changed to normal Ringer's solution. The sensitivity fell but, in the experiments so far, the original value did not return to that noted at the beginning of the experiment.

Auricular pressure during exercise in dogs with decreased cardiac competence and cardiac fail-

ure A C BARGER, B B ROE AND G S RICHARDSON (introduced by E M LANDIS) *Dept of Physiology, Harvard Med School, Boston, Mass*

To investigate the relation between cardiac competence, exercise and venous pressure (LANDIS *et al*, 1946) we have studied work tolerance and auricular pressure in dogs during exercise on the treadmill before and after the production of the following cardiac lesions a) pulmonary insufficiency, b) pulmonary stenosis, c) combined pulmonary stenosis and insufficiency, d) tricuspid insufficiency, and e) combined tricuspid insufficiency and pulmonary stenosis. Auricular pressure at rest in most normal dogs was close to zero, and did not change markedly during exercise. Pulmonary insufficiency had no measurable effect on auricular pressure at rest or during exercise, or on work tolerance. Pulmonary stenosis produced a slight elevation of resting auricular pressure with little further change during exercise (one exception). Work performance was normal, and the subsequent avulsion of the pulmonary valves had remarkably little effect. With tricuspid insufficiency resting auricular pressure was elevated 70-100 mm saline. Exercise produced a further rise of 50-100 mm saline, but no detectable decrease in ability to do work was found. Three dogs with tricuspid insufficiency were then subjected to pulmonary stenosis. Resting auricular pressure was 165-250 mm saline, and rose to as high as 425 mm saline during exercise of much lower intensity. All 3 dogs so treated developed a syndrome of cardiac failure, with marked reduction in work tolerance. Heart-lung preparations indicated clearly that cardiac insufficiency was present.

Effect of albumin on renal oxygen consumption in man HAROLD G BARKER, JOHN K CLARK, ARCHER P CROSLY AND ALVIN J CUMMINS (introduced by I S RAYDIN) *Harrison Dept of Surgical Research, School of Medicine and Hospital, Univ of Pennsylvania, Philadelphia*

Renal oxygen consumption has been generally thought to vary directly with changes in renal blood flow in contradistinction to other organs and the body as a whole where oxygen uptake remains constant when blood flow changes. This relationship has been reported by others with reduced renal blood flows but has not been previously tested at increased flow rates. The rapid iv administration of 75 gm of albumin was used in 5 normal human subjects as a means of increasing renal blood flow. Renal hemodynamic effects were essentially those observed by others, namely a large increase in renal blood flow (direct PAH Fick), variable or unchanged glomerular filtration rate (mannitol clearance), depressed PAH excretion, and a fall in hematocrit. In all 5 subjects

the renal A-V oxygen difference decreased approximately in proportion to the increase of renal blood flow so that renal oxygen consumption changed but little. The elevated renal blood flow following albumin is probably partly a result of renal vasodilatation secondary to the increased blood volume and partly due to decreased viscosity. The decreased filtration fraction probably indicates that the vasodilatation is in the efferent arteriole although in the absence of a direct method for measuring glomerular filtration rate it might be argued that albumin leads to reabsorption of the test substance. In one other subject we found no change in PAH Tm in the face of an increased renal blood flow following albumin. This makes a Trueta shunt (diversion from cortex to medulla) explanation of our findings unlikely.

Anti-thyroxine effects of thyroxine analogues

S B BARKER AND H B DIRKS, JR*, H M KLITGAARD,* S WAWZONEK* AND S C WANG* *Depts of Physiology and Chemistry, State Univ of Iowa, Iowa City*

Work has been continuing on the evaluation of potential inhibitors of thyroxine in a mammalian organism, the rat, using the following criteria: 1) lowering the BMR's of normal animals, 2) lowering the thyroxine elevated BMR's of thyroidectomized animals, 3) reversal of thyroxine depression of estrogen sensitivity of thyroidectomized animals. Among the compounds showing ability to overcome thyroxine effects were iodinated phenoxyacetic acids, 4-hydroxy- and 4-benzoyloxy-3,5-diodobenzoic acids, N-(4'-hydroxy-3', 5'-diodobenzoyl)-3, 5 diiodotyrosine, N-(2, 5-dihydroxyphenyl)-pyridinium acetate and 2 dimethyl-aminomethyl-dibenzofuran hydrochloride. The third test appeared to yield the most sensitive changes, with molar ratios of inhibitor thyroxine required to produce approximately 50% decrease in thyroxine effect being about 50:1 to 100:1. Considerably larger amounts were necessary in the other two procedures.

Electrolytes in the muscle of young chicks J S BARLOW* AND J F MANERY *Dept of Biochemistry, Univ of Toronto, Toronto, Canada*

The breast muscle of chicks, 3 days old, showed an entirely different electrolyte pattern from that of adult hen muscle. It contained 83% water, 10% more than the adult muscle. The chloride concentration (68.2 mEq/kg) was 8 times that of adult muscle, the sodium (96.6 mEq) was 3.5 times, while the potassium (45.5 mEq/kg) was about one-half that of adult muscle. In the chick serum, these constituents are not significantly different in concentration from that in adult serum. Good indirect evidence of the extracellular position of the muscle chloride was obtained in two ways. Firstly, the chloride diffused freely

from the muscle into Ringer's solutions in which the chloride had been replaced by nitrate. Secondly, the proportion of extracellular space measured histologically agreed well with the estimates of the extracellular fluid volume calculated from chloride analyses, i.e. about 50% of muscle volume. When this estimate of the extracellular volume was adopted, the intracellular potassium concentration was about the same as that of the adult muscle but a much larger intracellular sodium concentration was found. This sodium was found to diffuse freely into Ringer's solution in which sodium was replaced by potassium or by lithium and to exchange rapidly with radioactive sodium. The data suggest that the sodium not accommodated in the extracellular water is situated outside the cells, perhaps bound to some organic solid.

A transitory carbohydrate substance occurring in anaerobic assimilation of yeast cells J. PERCY BAUMBERGER AND FRANK W. FALES * *Physiology Dept., Stanford Univ. Med. School, Stanford, Calif.*

The authors previously showed (*J. Biol. Chem.* 173 1, 1948) that a large fraction of the sugar added to a yeast cell suspension goes temporarily into a nonreducing, nonhydrolyzable form. Further study has added the following information as to the characteristics of this 'hidden' sugar: 1) It is still in carbohydrate form as it is demonstrable by Dreywood's Anthrone Reagent which is specific for the hydroxymethylfurfural group, but it is insoluble and occurs inside the cell. It is not trehalose as it is not extractable by alcohol. 2) The 'hidden' sugar is a product of cell synthesis since its formation is inhibited by sodium azide at a concentration greater than that necessary to stop glycogen formation. 3) The 'hidden' sugar finally appears in the carbon balance sheet as the substrate is gradually depleted. It has therefore a transitory existence and its accumulation and disappearance follow a regular course. 4) Metabolically the 'hidden' sugar is characterized by being very rapidly fermented anaerobically. This is demonstrated by washing the yeast cells free of substrate at suitable stages in the course of the formation and breakdown of the intracellular 'hidden' sugar. The rate of fermentation of the washed cells is found to vary directly with their 'hidden' sugar content. 5) Similarly the 'hidden' sugar is very rapidly oxidized. This is demonstrated as above with washed cells. The cells are suspended in air saturated buffer and the oxygen consumption rate is followed polarographically. This rate is found to also vary directly with the 'hidden' sugar content.

Dual effect of positive intrapulmonic pressure on muscular response JOHN W. BEAN AND LEONARD

E. ELWELL * *Dept. of Physiology, Univ. of Michigan, Ann Arbor*

Application of positive intrapulmonic pressure causes an augmentation of tibialis anticus contractions elicited by slow (1-2/sec.) single shock motor nerve stimulation in anesthetized dogs. This has been tentatively ascribed to an influence on the neuromyal junction induced by the drop in blood flow (recorded by thermopile) which results from PIP application. The finding that augmentation occurred in direct stimulation of the normal muscle, but was missing in such stimulation of the chronically denervated muscle supports this interpretation. Furthermore, augmentation is also missing in curarized muscle. It was found, however, that curarization does not provide an entirely fair means of differentiation of effects, since it was demonstrated that curarization not only paralyzes the nerve endings, but also markedly depresses irritability of the muscle itself, both in the normal and chronically denervated preparation. In contrast with its augmentatory influence on contractions of low frequency, PIP invariably causes a profound diminution of contractions elicited by higher frequency of stimulation (10-20/sec. or above). PIP therefore exerts an incrementory influence on contractions of low frequency and a decrementory influence on contractions of higher frequency. The incrementory influence may be operative during higher frequency stimulation, but if so, it is entirely masked and superseded by the decrementory influence. This decrementory influence is attributed to the diminished blood flow and O₂ supply, but unlike the incrementory influence it is readily demonstrable in direct stimulation of the chronically denervated muscle.

Intestinal blood flow JOHN W. BEAN AND M. SIDKY MOHAMED * *Dept. of Physiology, Univ. of Michigan, Ann Arbor*

In an extension of work, reported earlier, the relation between blood flow into an isolated loop of dog intestine, perfused by heparinized dog blood, was studied by thermopile and drop methods. Findings that individual rhythmic contractions provide important propulsive force to blood flow, and that increasing rhythmic activity increases flow are confirmed and further demonstrated by the fact that the rhythmic contractile phase increases outflow but diminishes inflow, while the reverse is true of the relaxation phase. Flow is markedly affected by change in tonus; decreased tonus greatly augments flow, even in the absence of rhythmic contractions; increased tonus decreases, or even temporarily occludes the flow. Intermittent tonic contractions serve also in propulsion of blood. Tonic occlusion of flow is followed by a temporary supra normal flow, pro-

sumably due to temporary accumulation of vasodilator substances CO_2 (6-15%) increases flow, followed occasionally by a gradual diminution to below the pre- CO_2 level. These changes are attributed to an initial increase of gut activity, the subsequent pronounced quiescence and decreased tonus and to vasodilation. Low O_2 (7-10%) increases flow, decreases gut activity with slow recovery. Acetylcholine increases flow even in the absence of gut stimulation, with larger doses the increased flow is temporarily occluded by strong tonic contractions. Increased intraluminary pressure (12-20) mm Hg causes an initial short increase of outflow and a subsequent pronounced decrease of both inflow and outflow in spite of the augmentation of gut activity by the increased pressure.

Ketosis in diabetic rats CLARISSA H. BEATTY
Depts of Biochemistry and Physiology, Univ of Oregon Med School, Portland

Little ketosis occurs in fasting rats (BUTTS AND DEUEL *J Biol Chem* 100 415, 1933), therefore, ketosis in rats has usually been studied after administering ketotic substances such as butyric acid. While investigating the suitability of diabetic rats for studying the effect of various compounds on ketosis (West and Beatty, to be published), a high level of ketonuria was noticed in many alloxan diabetic animals. The first week following alloxan, ketonuria as high as 33-42 mg/100 gm/24 hr was found without comparably high urinary glucose or non-protein nitrogen excretion. Moreover, as ketonuria fell glucosuria and urinary non-protein nitrogen excretion frequently rose. During the following weeks ketonuria usually decreased to a lower and relatively constant level, then rose terminally. For weeks some rats maintained ketonuria above 4 mg/100 gm/24 hr, a value at least 5 times that of the non-diabetic animal. Depancreatized rats did not show this severe early ketonuria. In animals with sufficient pancreas removed to produce diabetes in 1-2 weeks, ketonuria commenced at low levels and, within a matter of days, reached plateau values between 3-5 mg/100 gm/24 hr. These animals were not followed to the terminal stages. When diabetic animals were fasted 24 hours, ketonuria fell to non-diabetic levels, and glucosuria decreased sharply. Restriction of food intake may result in a decrease in glucosuria without a comparable drop in ketonuria. These data indicate that some diabetic rats show sufficient ketosis to render them suitable for investigation of this metabolic upset.

Comparison of arterial O_2 saturation with tissue O_2 levels VIVIAN G. BEHRMANN, WALTER D. GRIEST*, GEORGE H. MANGUN* AND FRANK W. HARTMAN* *Dept of Laboratories, Henry Ford Hospital Detroit, Mich*

Continuous recordings of arterial O_2 saturation, tissue O_2 , respiration and blood pressure were obtained on anesthetized dogs. The blood O_2 saturation was recorded photoelectrically by the oxyhemograph while tissue O_2 concentration was determined voltametrically. Relative changes in available tissue O_2 were measured by inserting a tungsten wire electrode for a known distance into the tissue, and applying an Ag-AgCl electrode to a nearby convenient area. Across the terminals of this circuit an E M F of -0.66 v was applied, the resultant current, varying with available O_2 was amplified by a contact modulated D C amplifier and recorded by a D C milliammeter. O_2 concentration was measured in muscle, spleen, kidney, or liver during each procedure for the purpose of comparison. Hyperoxic as well as mild and severe hypoxic states were established by altering the O_2 content of the inspired air. The contour of the oxyhemograph and the tissue O_2 tracings show a striking similarity. Development of and recovery from hypoxemia were reflected by parallel changes in tissue O_2 except for a measurable time lag. Using the arterial O_2 saturation level as a control, one may compare the time lag and the extent of O_2 change in the tissues studied. Since it is obvious that the tissue O_2 consumption as well as its circulatory supply are prime factors in affecting the available O_2 concentration in the tissues, experiments were performed in which the tissue O_2 consumption was reduced by a histotoxic agent, (cyanide), and circulatory changes were created by vasomotor drugs.

Simultaneous high- and low-speed electromyography A. L. BENNETT AND A. L. DUNN*
Dept of Physiology and Pharmacology, Univ of Nebraska College of Medicine, Omaha

A method of recording action potentials with simultaneous, parallel, high- and low-speed traces upon the same photographic record has been developed and used in electromyography. A continuous trace from one C-R tube is recorded on paper (6 cm Electrocardiograph no 1115) moving at speeds from 5-20 cm/second. Simultaneously a second beam is repeatedly swept across the face of another 5 inch C-R tube so that high speed traces are made parallel to the continuous trace. The rapid traces are automatically repeated at regular intervals so that they form an almost continuous line. The linear speed of the sweep may be adjusted to provide a time-base of 1-10 millsec/cm. The necessity of replacing the conventional slit at the photographic surface with an opening large enough to accommodate each sweep introduces the problem of fogging due to background illumination. To prevent this a blanking circuit releases the beam only during the useful portion of the sweep on the one tube. The other tube is

masked with a slit aperture at the tube face. This method of recording has facilitated the analysis of single complexes from units which can be identified in terms of rhythm and rate of repetition in the parallel, continuous tracing. Such analyses have revealed wide variations in phase relationships and duration of complexes both from innervated and denervated muscle units. Often it is essential to have the combined recording in order to identify the type of unit which is spontaneously active.

New methods of direct calorimetry and dermal radiometry T. BENZINGER AND C. KITZINGER (introduced by EUGENE F. DuBOIS) *Naval Med. Research Inst., Bethesda, Md.*

Total caloric output can be continuously recorded as a single thermoelectric potential by means of the gradient calorimeter, with a sensitivity of 35 μ /watt, and a half response time of 4.2 sec. for the gradient layer (Benzinger, T. and C. Kitzinger *Rev. Scient. Inst.* In press, 1949). Radiated heat loss from the entire body surface can be continuously recorded as a single thermoelectric potential by means of the 4 π radiometer, with a sensitivity of 18 μ v/watt, and a half response time of 0.25 sec. The 4 π radiometer can be applied to the internal surface of a gradient calorimeter. The rapid response of each allows the study of reflex changes in peripheral circulation. (The index of peripheral circulation is obtained from total heat loss, average skin temperature, and rectal temperature, according to DuBois' and Hardy's formula, while average skin temperature follows from radiated heat output according to the Stefan-Boltzmann equation.)

Use of N-acetyl 4-aminoantipyrine in measurement of total body water in dog and man EUGENE Y. BERGER,* BERNARD B. BRODIE,* JULIUS AXELROD,* MARCELLE F. DUNNING,* YETTA POROSOWSKA* AND J. MURRAY STEELE *Research Service, Third (New York Univ.) Med. Division, Goldwater Memorial Hospital, New York City*

Antipyrine, because of its uniform distribution throughout the water of the body and its slow rate of excretion and transformation, has been used in the measurement of total body water in man. It is impractical to use for this purpose in dogs, however, because the rate of transformation is too rapid in this species. A derivative of antipyrine, N-acetyl 4-aminoantipyrine, has also been found to distribute in tissues in proportion to the water content. In addition, its metabolic alteration is slow enough in the dog to permit its use in this animal in the measurement of the total body water. In contrast to antipyrine, which is bound to a small extent on plasma proteins, N-acetyl 4-aminoantipyrine is only negligibly bound. Preliminary comparisons of the volumes of distribution of antipyrine and N-acetyl 4-aminoanti-

pyrine were carried out in man. The agreement was good enough to suggest that N-acetyl 4-aminoantipyrine may be useful in both man and dog as a measure of body water. N-acetyl 4-aminoantipyrine has certain advantages over antipyrine for use in man. Its estimation involves a colorimetric procedure which, though somewhat less accurate than that of antipyrine, does not require an ultraviolet spectrophotometer. The compound is almost quantitatively excreted in the urine so that if its urinary excretion is measured, the volume of distribution may be calculated on the basis of a single plasma level.

Effect of reduced cardiac output on renal circulation ROBERT M. BERNE AND MATTHEW N. LEVY (introduced by CARL J. WIGGERS) *Dept. of Physiology, Western Reserve Univ. Med. School, Cleveland, Ohio*

Cardiac output was acutely reduced in open-chest dogs anesthetized with pentobarbital by means of graded constriction of the pulmonary artery. Glomerular filtration rate and renal plasma flow were measured by creatinine and PAH clearances, respectively. The Fick principle was used to determine cardiac output. Experiments were divided into periods of preoperative and postoperative controls, of pulmonary artery constriction, and recovery following release of constriction. Compression of the pulmonary artery sufficient to elevate central venous pressure without lowering mean arterial pressure below 80 mm. Hg resulted in a fall in cardiac output and renal blood flow. The latter fell proportionately less than the former, yielding an elevated renal fraction. Values returned toward control level upon release of the constriction. Glomerular filtration rate either remained constant or fell slightly, while the filtration fraction rose uniformly. With reduction of cardiac output, total peripheral resistance increased to a much greater degree than did renal resistance, and tended to return toward control level with release of the pulmonary artery. Renal resistance remained elevated and showed no statistically significant change between periods of constriction and release. Application of Lammport's formulae to our data reveals a decrease in afferent and an increase in efferent arteriolar resistances and a slight increase in post-arteriolar resistance. These studies suggest that the reduced renal fraction of congestive heart failure is not directly due to a reduction in cardiac output per se.

Metabolism of leukemic cells *in vitro* ROBERT M. BIRD, JOHN A. CLEMENTS AND LILLIAN M. BECKER (introduced by F. GLADENATSCHE) *Dept. of Physiology, Cornell Univ. Med. College, New York City*

The metabolic characteristics of leukocytes obtained from peripheral blood of leukemic patients

in relapse have been studied *in vitro*. Data derived using the Summerson constant volume differential manometer were compared with chemical analyses for glucose utilization and lactic acid production. Leukocytes from both myelogenous and lymphatic leukemia exhibited an oxygen consumption averaging 1.1 c mm/mg dry wt/hr with a Respiratory Quotient of 0.85. Those from myelogenous leukemia were characterized by a moderate glycolysis, total aerobic acid production averaging 5.6 c mm/mg/hr, lactic acid formation, 16 μ g/mg/hr, and glucose utilization, 28 μ g/mg/hr. Glycolysis in leukocytes from lymphatic leukemia was very low, the rate being about one-fifth of that of myelogenous leukemic cells. Anaerobic glycolysis was also greater in myelogenous leukemia averaging 9.2 c mm/mg/hr as contrasted to 3.1 c mm/mg/hr in lymphatic leukemia. Factors influencing the metabolic rates were studied. When the total number of leukocytes in the experimental vessel was below 25×10^6 per ml, all rates tended to be elevated. When the proportion of myeloblasts exceeded 60%, oxygen consumption was significantly increased and glycolysis depressed. Specimens obtained from patients with myelogenous leukemia under treatment with urethane or radiation showed average rates lower than the untreated group, but the difference of the means was not statistically significant. By altering the pH of the medium from 7.5 to 7.1, anaerobic glycolysis was reduced. Leukocytes from non-leukemic patients exhibited metabolic rates slightly higher than those of untreated leukemia.

Inactivation of posterior pituitary antidiuretic hormone by liver extracts JAMES H. BIRNIE (introduced by ROBERT GAUNT) *Dept of Zoology, Syracuse Univ, Syracuse, N Y*

The *in vitro* studies of Heller and Urban and the *in vivo* observations of Eversole, Birnie and Gaunt indicate that the liver plays an important role in the inactivation of posterior pituitary antidiuretic hormone. We have attempted to determine some of the properties of the system (enzyme) responsible for this inactivation. Systems capable of destroying both the antidiuretic and chloruretic activities of pitressin during *in vitro* incubation have been found in cell-free extracts of liver tissue. Preparations from kidney, spleen, whole blood and skeletal muscle contained some but progressively less activity. The inactivating system from liver tissue appears to have the properties of an enzyme. It is heat-labile, being destroyed by exposure to 80°C for 10 minutes. Optimum activity during incubation is between pH 6.2 and 7.5. At pH 6.5 the rate of inactivation of pitressin increases appreciably with a rise in temperature from 0° to 37°C. Further increases in temperature are associated with a sharp decline

in activity. One ml of a 1-10 aqueous extract adjusted to pH 6.5 is capable of inactivating 100 millunits of pitressin in 30 minutes at 37°C. The activity of liver extracts is almost quantitatively removed through adjustment of the reaction to pH 5.2 or by half-saturation with ammonium sulphate at pH 6.5. Activity of the enzyme is destroyed by exposure to 0.0005 M CuSO_4 or ZnSO_4 . Liver extracts also destroy the pitressin-like antidiuretic activity of fresh rat blood serum. There is a decrease in the pitressin-inactivating ability of extracts prepared from livers of rats following adrenalectomy. This may help explain the rise of serum antidiuretic substance after adrenalectomy and contribute to an understanding of the altered water metabolism in adrenal insufficiency.

Effect of exercise on renal function in dogs WILLIAM D. BLAKE (introduced by JOHN R. BROBECK) *Lab of Physiology, Yale Univ School of Medicine, New Haven, Conn*

Kattus *et al* (*Bull Johns Hopkins Hosp* 84:344, 1949) have demonstrated that in man the assumption of the upright position and the act of walking may reduce the percentage of filtered sodium excreted without any associated decrease in glomerular filtration rate. In order to evaluate further this response in terms of mechanisms, similar studies are being conducted on dogs. The usual clearance techniques are being used to estimate renal function. The intravenous infusion of creatinine, para-aminohippurate and NaCl in solution is maintained throughout the course of the experiment. After the collection of 2 or 3 urine samples at rest the dog is exercised on a treadmill especially constructed for the purpose. The collection of urine samples is continued immediately after the cessation of exercise and for several periods thereafter. In some experiments it has been possible to demonstrate a reduction in sodium excretion coincident with and immediately following exercise without change in filtration rate but this has not been an invariable finding. The possible mechanisms responsible for this change in sodium excretion, when it occurs, will be discussed.

Pigment layer factor in visual purple regeneration

ALFRED F. BLISS *Dept of Physiology, Tufts College Med School, Boston, Mass*

Hosoya and Sasaki (*Tôhoku J E Med*, '38) reported that partly bleached visual purple regenerated almost completely in the dark if extracted from retinal tissue containing an excess of the black pigment layer of the eye. We have investigated some properties of the pigment layer factor with the aid of extracts of visual purple prepared as follows. The rods from dark adapted frog retinas were centrifuged from 2.3 sucrose-water solution (Saito, *ibid*). Their visual purple

was extracted with aqueous digitonin. The extract at pH 6.5 was divided into 2 parts which were simultaneously bleached 90% in 1 minute by white light. One of the pair was immediately treated with alkaline sodium desoxycholate to prevent regeneration (CHASE AND HAIG, *J G P*, '38). After 2 hours in the dark at 25° the other was similarly treated, and both were then completely bleached to determine the regenerated visual purple as the difference between the falls in optical density of the 0- and 2-hour samples. This method was necessary because much of the density was due to photostable material. Such unfortified rod extracts gave no significant regeneration. Regeneration was best induced by adding 0.5 M NaCl extracts of fresh or lyophilized frog pigment layer homogenates to the visual purple. Water extracts were inferior. Salt extracts of beef pigment layer were about 0.1 as active as frog. Frog brain, liver and ATP were inactive. The amount of regenerated visual purple seemed more dependent on the amount of pigment layer than on the degree of bleaching. The factor was destroyed in 1 minute at 100°, but was not inactivated by dialysis against salt, or by alcohol or ammonium sulfate precipitation in the cold.

Cardiac output in the rat and its relationship to air embolism F. R. BLOOD* AND F. E. D'AMOUR
Biologic Research Laboratories, Univ. of Denver, Denver, Colo.

A method has been developed for determination of cardiac output in the rat at normal and simulated high altitudes using the Fick principle. The rat is anatomically suitable for this technic since it is possible to introduce a small metal tube directly into the heart through the jugular vein through which samples of mixed venous blood can be obtained. The cardiac output in the rat at Denver's altitude was found to be 46.5 cc/min. When the altitude was increased it was found that the cardiac output decreased and that the occurrence of air embolism was in some way related to the relative decrease in cardiac output. There was a significant difference in the cardiac output at high altitude in rats developing air embolism as compared with those in which no embolism developed. Animals with a cardiac output greater than 20 cc/min. did not develop air embolism while, in most cases, those with a cardiac output less than this value did show air embolism at autopsy.

Free energy efficiency of assimilation of acetate and ethanol by *Chilomonas paramecium* J. J. BLUM* AND JOHN O. HUTCHENS
Dept. of Physiology, Univ. of Chicago, Chicago, Ill.

Excess heat produced when measured amounts of acetate or ethanol were added to cultures of *Chilomonas* was measured using a differential microcalorimeter. Measurements were made with

and without a nitrogen source present. Fraction of substrate assimilated, and free energy efficiency of assimilation were calculated. With no N-source (only starch and fat synthesized) 59.8% of added acetate and 81.9% of ethanol were assimilated. The free energy efficiencies of assimilation are 26.4% and 19.8% respectively. Assuming only starch to be synthesized yields slightly higher values for assimilation, 63.4% for acetate and 87.2% for ethanol, with corresponding efficiencies of 31.0% and 23.4% respectively. To calculate free energy efficiency of assimilation of ethanol, the cost of synthesis of starch and fat from acetate was employed. Available energy was taken as the sum of that necessary for conversion of all the ethanol to acetic acid plus that available from oxidation of 18.1% of the acetate. The data indicate that the energy from the ethanol to acetic conversion must be used in part. With a nitrogen source (ammonia) present ca. 43% of acetate appeared to be assimilated (Compare 55% estimated from carbon balance sheets by HUTCHENS *et al.*, *J. Cell Comp. Physiol.* 32, 117, 1948). With protein involved, precise calculations of percentage assimilation based on thermal data are impossible at present as are calculations of the free energy cost of protein synthesis. Dependence of percentage assimilation on the nature of end products may depend on 1) cost of protein synthesis, 2) efficiency of protein synthesizing mechanisms or 3) complex kinetic phenomena.

Action of M.B., 2,4-DNP, NaN₃, and ethyl carbamate on oxygen uptake of mitotically active and blocked embryonic cells JOSEPH HALL BODINE
Zoological Lab., State Univ. of Iowa, Iowa City

An extensive quantitative study has been made on the effects of these compounds upon the oxygen uptake of mitotically active and blocked grasshopper embryos. Pure solutions as well as combinations of reagents have been employed. The cellular respiratory mechanism is approximately 60% sensitive and 40% insensitive to ethyl carbamate and sodium azide in reversible doses. Methylene blue exerts its marked stimulating effects upon the 60% sensitive fraction while 2,4-dinitrophenol exerts its stimulating action upon the 40% insensitive fraction. Apparent antagonisms between such compounds as methylene blue, ethyl carbamate and sodium azide are thus readily explained. Sodium azide has little if any effect upon the oxygen uptake of mitotically blocked embryonic cells.

Influence of phlorhizin on intestinal absorption of hexoses E. M. BODANOV* AND S. B. BARKER
Dept. of Physiology, State Univ. of Iowa, Iowa City

Hexose absorption experiments on anesthetized rats gave the following coefficients of absorption (mg. absorbed per 100 gm./hr.) in glucose 116.6

D-galactose 101.2, D-fructose 49.3, D-mannose 19.9, L-sorbose 7.1 Phlorhizin (subcutaneously in oil) inhibited significantly the absorption of glucose (38%) and galactose (44%). Fructose absorption in phlorhizinized rats was 28% greater than in controls. The effect of phlorhizin on mannose (-26%) and sorbose (-90%) was not statistically significant. The normal coefficients were lower than those obtained by Cori and others in unanesthetized rats, indicating a general depression of the absorption processes by anesthesia (Nembutal). The lower coefficients were, however, in the same relative order, except for galactose. The difference between glucose and galactose coefficients in these experiments is not statistically significant. The lack of phlorhizin inhibition for fructose absorption is in contrast to previous reports and may indicate the presence of fructose phosphorylating and dephosphorylating enzymes resistant to phlorhizin action.

Adrenal stress and metabolism of ascorbic acid

WALTER M. BOOKER, RAYMOND L. HAYES* AND FRANCES M. DENT * *Depts of Pharmacology and Oral Medicine, Howard Univ College of Medicine and Dentistry, Washington, D C*

Animals under stress, given ascorbic acid, excrete more ascorbic acid in the urine than is given, indicating not only an inability to control the administered ascorbic acid, but a loss of ability to hold the stored ascorbic acid. When groups of animals under stress are given the same amount of ascorbic acid as the above group and are injected with adreno-cortical extract, the urinary excretion is significantly less and the plasma and cell levels are higher. In the ACTH treated groups, the urinary ascorbic acid rises to reach a peak by the 3rd day and falls on the 4th day. When ACTH animals are given ascorbic acid, the urinary output of ascorbic acid is higher by the third day than that of the ACTH treated above. The drop is similar to the above group, although not as great. The ACTH group, antagonized by ACE, shows a much less urinary output of ascorbic acid, and when given ascorbic acid, the urinary excretion is much less than the ACTH-ascorbic acid group. The evidence seems to show that day-to-day injections of ACTH stresses the adrenals to such a degree that the content of the ascorbic acid decreases. ACE antagonizes this stress, although at the present dosages have not been worked out between the two substances where the effects of ACTH have been off-set. ACTH animals show a decrease in adrenal ascorbic acid, with an increase in adrenal cholesterol. ACE treated animals tend to reverse this picture. ACTH treated animals show a low plasma ascorbic acid level as compared with those treated with ACE and ACTH,

but the ascorbic acid tends to hold fairly well in all ACTH treated groups.

Influence of adreno-cortical hormone on the day-to-day blood levels and excretion of ascorbic acid in dogs

WALTER M. BOOKER, RAYMOND L. HAYES* AND FRANCES M. DENT * *Depts of Pharmacology and Oral Medicine, Howard Univ College of Medicine and Dentistry, Washington, D C*

To study the possible rôle of the adreno-cortical hormone in the maintenance of blood levels from day to day, dogs were arranged in 4 groups. *Group I* dog chow plus 30 gm of Delcos granules per day, *Group II* 200 mg ascorbic acid plus 30 gm of Delcos granules per day plus dog chow, *Group III* 200 mg ascorbic acid plus 30 gm of Delcos granules per day plus 0.1 cc adreno-cortical extract plus dog chow, *Group IV* vitamin C free dog chow plus 30 gm of Delcos granules. Plasma and cell ascorbic acid, as well as urinary ascorbic acid, were determined daily. Cholesterol, chlorides, sodium and potassium were determined on each animal daily. The experiments ran 2 weeks. The plasma levels of the animals receiving ascorbic acid plus adreno-cortical hormone were consistently higher than any other group during the first week. During the second week, the plasma levels of the adreno-cortical treated animals (*Group III*) were not markedly higher than the plasma levels of animals receiving only ascorbic acid (*Group II*), but the blood cell levels were much higher than this group. The lowest plasma levels, as expected, were in the vitamin C free group (*Group IV*), but the cell levels of this group did not fall until after the plasma level had fallen significantly during the beginning of the second week. Blood cell conservation of vitamin C is suggested. When the regimen of the groups was rearranged after a 2-week run giving cortical extract to *Group II*, no extract to *Group III* and ascorbic acid to *Group IV*, the group receiving cortical extract continued to show the highest blood levels of vitamin C.

Further studies on the vomiting center

H. L. BORISON* AND S. C. WANG *Dept of Physiology, College of Physicians and Surgeons, Columbia Univ, New York City*

Chronic lesions in the *ala cinerea* of the medulla oblongata (vomiting center of Hatcher and Weiss, 1923) in 5 dogs increased the intravenous apomorphine threshold for emesis to an indeterminate level (more than 50 times control), whereas the threshold to orally administered CuSO_4 was increased only slightly. Thus, the vomiting center is not located in the *ala cinerea*, rather, the latter constitutes an afferent station for the emetic response. Lesions in the floor of the IVth ventricle

extending into the dorsolateral portion of the reticular formation (reactive area for emesis by electrical stimulation, Borison and Wang, 1949) have resulted in significant increases in CuSO_4 threshold as well as marked refractoriness to apomorphine. It follows therefrom that the center for emesis resides in this deep structure of the medulla. Attempts are now being made with the use of small radon implants to destroy a circumscribed portion of the lateral reticular formation without damaging the floor of the IVth ventricle. Dogs in which all afferent pathways from the gastrointestinal tract have been severed still vomited to orally administered CuSO_4 but only to large doses and with latencies prolonged to a minimum of 90 minutes. The long delay suggests that the response is due to the action of absorbed copper. This contention is supported by the fact that CuSO_4 injected intravenously elicits emesis within 3 minutes. The emetic response to intravenous copper, like apomorphine, was not elicitable after destruction of the *ala cinerea*, thus indicating that this structure serves as a chemoreceptor for emesis.

On the nature of the elastic mechanism in actomyosin threads JEAN BOTTS AND MANUEL MORALES (introduced by KENNETH S. COLE) *Naval Med Research Inst, Bethesda, Md, and the Dept of Physiology, Univ of Chicago, Chicago, Ill*

Thermodynamic analysis of tension as a function of temperature for various extensions permits resolution of tension into 'entropy and enthalpy forces'. For small extensions of a thread maintained wet ('native') the positive tension was entirely entropic, the enthalpic contribution was negative. The reverse resulted in threads allowed to dry under stretch ('vulcanized') and then re-wet. Electron microscope and thread solubility studies showed that substances capable of hydrogen bonding inhibited gelation of actomyosin to an extent roughly paralleling their bonding ability, suggesting that hydrogen bonds, as well as purely electrostatic attractions, were responsible for maintaining the actomyosin network, especially as regards infra-filamentary linking. Absorption studies in the near infra red tended to confirm the foregoing observations. If the enthalpy be taken to approximate the internal energy, the native thread corresponds exactly to the state of resting muscle postulated by Bull, and more recently by Riseman-Kirkwood and Katchalsky, for its 'rest length' seems a compromise between an entropic contractile force and an electrostatic repulsion between charges fixed along the linear elements. Presumably on neutralizing the charges the system would contract under a purely entropic force. An earlier thermodynamic study by Woods

on myosin films probably employed a system 'vulcanized' in the extended state. Whether the actomyosin within the muscle fibril is more nearly in the 'native' or the 'vulcanized' state now becomes an important issue to settle.

Experimental differential inflow obstruction in dogs' hearts ROBERT J. BOUCEK,* JOHN H. GRINDLAY *Mayo Clinic, Rochester, Minn*

Cellophane bands placed about the venae cavae for periods of 5 days resulted in a reproducible picture of circulatory failure related to obstruction of right inflow which was progressive for 2 weeks and was followed by complete recovery after 4 weeks. The failure was characterized by a subnormal arterial pressure (av, 80 mm Hg), parallel reduction in glomerular filtration, renal plasma flow and urinary output (av, $\frac{2}{3}$ of normal). Increases in venous pressure (av, 100 mm H_2O) became established after the appearance of ascites and edema. The blood volume was normal, as was the value for serum protein, the protein content of the ascitic fluid was high (av, 3.4 gm %). Obstruction of left inflow, successfully produced in one animal, by the placing of cellophane bands about the pulmonary veins, resulted in severe hyperpnea with markedly increased roentgenologic density in the lung fields. This was followed by generalized edema. The volume of circulating blood was increased. Glomerular filtration, output of urine and arterial pressure remained normal. A slight increase in venous pressure occurred late after failure became evident. Acute pericarditis produced by Dakin's solution resulted in either of the two types of failure or a combination thereof. One type resembled the late phase of right-inflow stasis with a high venous pressure and an abrupt occurrence of ascites. The second type of failure resembled the picture of left-inflow stasis, with minimal change in renal function, a large increase in blood volume, and the occurrence of pulmonary edema, followed later by a slight increase in venous pressure and by edema.

Factors in hyperpnea of bronchial obstruction and atelectasis HARBEN J. BOUTOURLINE-YOUNG* AND JAMES L. WHITTENBERGER *Dept of Physiology, Harvard School of Public Health, Boston, Mass*

This investigation was prompted by the observation that in 3 newborn infants with atelectasis who were stimulated with electrophrenic respiration there was a reduction of 20-25% in minute volume during subsequent spontaneous respiration. This appeared to accompany expansion of the lungs, presumably a decrease in atelectasis. In dogs under various types of anesthesia, there was a consistent increase in respiratory minute volume following obstruction of one main

bronchus Thus the unobstructed lung was being ventilated at a rate generally more than twice its previous level The results were not affected by the use of local anesthesia at the site of obstruction Evidence was adduced for the following factors in hyperpnea a) *Mechanical* Because of the decreased expansion of the obstructed lung with inspiration, the intrapleural negative pressure was raised and the other lung accordingly expanded more b) *Dead space* The upper airway composes a given fraction of the total lung volume, in bronchial obstruction the alveolar space is approximately halved, without proportionate reduction in upper airway dead space The ratio of alveolar space to dead space is therefore decreased, resulting in increased ventilation requirements to maintain normal $p\text{CO}_2$ c) *Chemical* Although arterial oxygen saturation was reduced during obstruction, arterial CO_2 values remained normal, indicating that in this type of insult to lung function, the perfusion-ventilation ratio compensates for impaired CO_2 elimination, but not O_2 uptake d) *Reflex* Ventilatory reflexes due to local chemoreceptor or pressoreceptor stimulation have not been fully evaluated

Superprecipitation of actomyosin by inosine triphosphate WILLIAM J BOWEN AND S S SPICER * *Experimental Biology and Medicine Inst , Natl Insts of Health, Bethesda, Md*

Superprecipitation of actomyosin by adenosine triphosphate (ATP) is described by Spicer and Gergely in another abstract The addition of inosine triphosphate (ITP) instead of ATP is without effect, but if 0.3 ml of aqueous muscle extract (prepared by extracting muscle with 2 volumes of water) is added with ITP, superprecipitation does occur Muscle extract deproteinized with 2% perchloric acid is more effective than the original extract Ash from deproteinized muscle extract retains about 25% of the activity of the extract ITP with 0.001M MgCl_2 causes complete superprecipitation Superprecipitation does not occur when muscle extract or any of the above preparations from it are added without ITP The superprecipitations by ITP and ATP, respectively, differ in that approximately twice as much ITP (1.0 mg) as ATP is required and that superprecipitation by ITP requires 5 times longer (approx. 5 min) than that by ATP These results indicate that an organic factor, in addition to Mg, must be supplied for ITP to cause superprecipitation The possibility exists that ITP acts by being converted to ATP If this is true, then it should be possible to demonstrate spectrophotometrically the formation of adenine in this reaction Also, myokinase in the presence of myosin (since myokinase removes ADP by dismutation but not IDP) would cause larger quantities of inorganic phosphorus to be liberated

if ATP is formed than if not Both of these approaches were tested and neither gave evidence of formation of ATP Experiments are now in progress to determine whether this effect of ITP in the presence of muscle extract can be explained on other bases

Role of the vagus in control of respiration EMIL BOZLER AND B H BURCH * *Dept of Physiology, Ohio State Univ , Columbus*

To determine the role of the pulmonary afferent fibers the following experiment was carried out One end of a thin rubber tube was attached to the left vagus of an anesthetized dog just above the hilum The tube was passed through the back to the outside The right vagus was cut in the neck After the chest was closed and normal respiration was resumed, 0.2 cc of 2% cocaine was introduced through the tube to block the vagus The block abolished the Hering-Breuer reflexes and produced the following changes in respiration 1) The amplitude of respiration was diminished, 2) respiratory rate was increased, 3) The speed of the inspiratory act was markedly diminished The differences between these results and those of cervical vagotomy probably are due to the presence of extrapulmonary vagal fibers influencing the rate of respiration and to the discharge of impulses from the cut end of the nerve It may be concluded that vagal afferent fibers have a strong augmenting effect on inspiration as suggested by Gesell This effect is not caused by mechanical receptors because vagal block slows inspiration also while the chest is open and while respiratory movements and lung inflation are asynchronous and because this effect does not depend on the volume of the lungs Afferent impulses of pulmonary origin are predominantly excitatory and exert a continuous drive on respiration

Water and electrolyte excretion by the harbor seal (*Phoca vitulina*, L) S E BRADLEY, G H MUDGE* AND W D BLAKE * *Dept of Medicine, Columbia Univ College of Physicians and Surgeons, New York City, and Mt Desert Island Biological Lab , Bar Harbor, Maine*

Measurements of glomerular filtration rate by the creatinine clearance and of urinary sodium, potassium and water output have been made in 24 studies of 6 weanling Harbor Seals under varying conditions of hydration and food intake, and during diving apnoea The post-prandial renal hyperemia and apneic ischemia with corresponding changes in glomerular filtration, detected in earlier studies and confirmed in these, provided an opportunity to examine the relationship between filtration and water or electrolyte excretion In general, water and electrolyte output changed in the same direction as the filtration rate However, sodium,

potassium or water loading resulted in increased excretion, in large part as a result of decreased tubular reabsorption independent of changes in filtration. Water diuresis was associated with diminished sodium and potassium output. Pitressin and mercupurin had opposite effects on water excretion, but both augmented the elimination of electrolytes. It is interesting that a marked fall in output and urinary concentrations of sodium and potassium occurred in association with reduced filtration during apnea despite preliminary loading or administration of a mercurial diuretic. These results suggest that glomerulotubular imbalance may develop during renal ischemia in the seal and give rise to a relatively excessive reabsorption of electrolyte from the glomerular filtrate. The creatinine U/P ratio tended to fall during apnea indicating that water reabsorption was relatively decreased. This phenomenon could not be explained by reduced pituitary activity since it was observed in one animal during apnea following pitressin. However, the creatinine U/P ratio rose during apnea following sodium load, suggesting the possibility that effective water reabsorption may depend in part upon a critical concentration of sodium in the tubular urine.

Influence of respiration upon the dynamics of experimental atrial septal defects G A BRECHER AND D F OPDYKE *Dept of Physiology, Western Reserve Univ Med School, Cleveland, Ohio*

Since it is established that left atrial pressure exceeds right atrial pressure during most of the cardiac cycle in open-chest dogs it is important to know what effect changes of intrathoracic pressure have on the interatrial pressure gradient. Interatrial septal defects were produced, the chest closed, and the effect of changing intrathoracic pressure studied in acute experiments. When the left to right inter-atrial pressure difference was small during the expiratory pause the pressure gradient became reversed for a longer duration of the cardiac cycle during inspiratory movements. Rapid and extensive intrathoracic pressure decreases caused a greater and longer lasting gradient reversal. During dyspneic inspiratory movements the atrial pressure reversal lasted in some cases for several consecutive cardiac cycles. Neither alternating positive pressure inspirations with an artificial respirator nor maintained increased positive intrathoracic pressure during Valsalva-type experiments caused a reversal of the left to right inter-atrial pressure gradient. The importance of the respiration for a reversal of the blood flow through an interatrial shunt can be evaluated by an analysis of the phasic changes of atrial pressure curves.

Carbohydrates in human cervical mucus MARY ALICE B BRECKENRIDGE* AND W T POMMER-

ENKE *Dept of Obstetrics and Gynecology, Univ of Rochester Med School, Rochester, N Y*

That human cervical mucus is penetrable by sperm *in vitro* only at the ovulatory phase of the menstrual cycle has been demonstrated. *In vitro* studies also indicate that human sperm are dependent on anaerobic glycolysis for motility. Carbohydrates are present in the female genital tract, and the possibility that these are utilized in sperm metabolism presents itself. This work on cervical mucus has been continued to identify, by a chromatographic method, the carbohydrates and to quantitatively estimate individual simple sugars and polysaccharides throughout the menstrual cycle. In 6 normal subjects, followed through a total of 14 cycles, glucose was the only simple sugar consistently found, and the 0-36 mg % glucose showed no consistent cyclic variation. Whether or not the free glucose is utilized by sperm in passage through the cervical canal, it would appear that the glucose content of the mucus is not a factor in the cyclic penetrability.

Adrenal function in gravitational and acceleratory shock S W BRITTON AND C R FRENCH* *Physiological Lab, Univ of Virginia, Charlottesville, Va*

Normal rats are very resistant to the head-up position on the tilt-table, and survive for 12-48 hours, although considerable torpidity is shown throughout the period. Respiratory and various reflex activities may be used as criteria of an animal's condition. Hyperglycemia occurs within the first few hours, followed by prolonged hypoglycemia. In 30 tests made 1-7 days after bilateral adrenalectomy, marked sensitivity to the vertical posture was shown, some animals died within one hour, and most of the others became comatose or died within 2 hours. Operated rats treated with cortico-adrenal preparations showed resistance to gravity almost equal to normal animals. Adrenaline administration only slightly improved tolerance. On exposure to accelerations on the centrifuge, adrenalectomized rats showed extreme sensitivity, in 26 cases, 11 died and all others were comatose within 12 min at 2 g. This was a relatively mild exposure for normal animals.

An inhibitor of insulin-inactivating system (insulinase) of liver ROBERT H BROTH-KAHN, BEN SIMKIN* AND I ARTHUR MIRSKY *May Inst for Med Research, Jewish Hospital, Cincinnati, Ohio*

Previous studies have demonstrated the existence in liver extracts of a system (insulinase) capable of inactivating insulin during *in vitro* incubation. During the process of purification of this system by acetone precipitation it was noted that the redissolved precipitates containing the insulinase activity, when reconstituted to their original

volume, were more active than the crude extracts. This observation indicated the presence of an insulinase-inhibiting substance in the crude extract and in the supernatant from the acetone precipitate. The existence of this inhibitor has been confirmed and it has been partially purified by adsorption on charcoal, and elution with glacial acetic acid followed by precipitation with absolute alcohol-petroleum ether mixtures. Concentrates of this substance are quite active and completely suppress the *in vitro* destruction of insulin by insulinase but do not inhibit the action of the more common proteolytic enzymes. Intravenous injection of large amounts have no effect on the blood sugar of the fasting rabbit. The distribution and properties of this inhibitor will be described.

Origin of the cerebellar waves JOHN M. BROOKHART, G. MORUZZI* AND R. S. SNIDER *Depts of Physiology and Anatomy, Northwestern Univ Med School, Chicago, Ill*

Spike potentials of single cerebellar neurons superimposed upon a baseline of typical cerebellar waves have been recorded from the cerebellar cortex in unanesthetized decerebrate cats using fine, penetrating wire electrodes and conventional oscilloscopic recording equipment. Localization of the tips of electrode wires left *in situ* was accomplished by microscopic examination of thick, fixed, stained and cleared blocks of cerebellar tissue. Low voltage wave activity and freedom from spike potentials characterized recordings from the molecular layer and white matter. Higher voltage waves, occasional spike potentials, and massive injury discharges upon movement of the electrode characterized recordings from the Purkinje cell and granule cell layers. These findings indicate the great localizing ability of the wire electrode and the origin of the cerebellar waves from the Purkinje and/or granule cell layers. Temporary cerebellar ischemia or administration of ether produced abolition of spike potentials before wave activity was affected. This change was reversible, wave activity recovering before spike potentials. Summation of spikes of the type recorded from these electrodes cannot therefore be considered as a source of cerebellar waves. The waves may originate from spike potentials of small, unmyelinated axons having a selectively high resistance to anoxia, or from variations in the state of polarization neural membranes, or from some unknown source.

Excitability of mammalian heart during the cardiac cycle the auricle CHANDLER! McC BROOKS, OSCAR ORIAS,* JEROME L. GILBERT,* ARTHUR A. SIEBENS,* BRIAN HOFFMAN* AND E. E. SUCKLING* *Dept of Physiology and Pharmacology, Long Island College of Medicine, the State Univ of New York, Brooklyn*

Excitability of the auricle throughout the cardiac cycle is determined by observation of stimuli needed to produce extrasystoles. Stimuli are applied to the auricle through attached non-polarizable electrodes from a stimulator delivering rectangular waves of variable intensity (from 0 to 30 ma) and duration (from 0.1 to 15 msec). The heart is driven by a pulsing-oscillator at any desired rate. Single testing stimuli can be applied at any position in the cardiac cycle within an error of ± 2 msec. Strength-duration curves are obtained and reveal that transition from an absolutely refractory state to a normal resting state of excitability is not smoothly progressive. Within the relative refractory period there are intervals of greater followed by intervals of lesser excitability as recovery proceeds. No supernormal-period is found. The latency between testing stimulus and the response increases progressively as the stimuli are placed earlier in the refractory period. A local excitatory state created by a single strong testing stimulus may outlast the refractoriness which follows normal driven beats. Progressive increases of testing-shock intensity at any instant within the 'vulnerable-period' produce first extrasystoles, then fibrillation and finally no response at all (a 'disappearance-phenomenon'). The 'disappearance-phenomenon' is thought to be due to large field effects of very strong stimuli. Like fibrillation, it can be obtained only during a 'vulnerable' portion of the relative refractory period.

Some biological and chemical properties of the citrovorum factor HARRY P. BROQUIST,* E. L. R. STOKSTAD AND T. H. JUKES *Lederle Labs Division, American Cyanamid Co., Pearl River, N. Y.*

Recent studies have indicated that concentrates of natural materials active for growth of *Leuconostoc citrovorum* reverse the toxicity of folic acid antagonists for some microorganisms under conditions in which pteroylglutamic acid (PGA) is ineffective. In the present study further evidence for the ability of citrovorum factor (CF) concentrates to reverse 4-amino PGA for *L. citrovorum* was found. In studies with mice it was found that CF concentrates given either in the diet or by injection could protect mice against the toxic effects of 4-amino PGA. PGA was without effect in alleviating this toxicity. In counter current distribution studies by the method of Craig, it was found that the distribution curves for CF activity or folic acid activity were indistinguishable. In other experiments it was found that CF was readily converted by exposure to HCl to a compound with properties similar to folic acid. These findings coupled with the ability of CF concentrates to reverse the toxicity of 4-amino PGA in microorganisms and mice support the view that CF is

a hitherto unrecognized biologically active form of PGA

Secretion of the gluconeogenic factor by the adrenal KATHARINE A BROWNELL *Ohio State Univ, Columbus*

The gluconeogenic factor secreted by the dog adrenal was assayed by virtue of its ability to cause deposition of liver glycogen. Blood was collected from the left lumbo-adrenal vein, tied at its entrance to the vena cava in a heparized nembu-talized dog. Transfusion of blood from a donor dog replaced that removed from the subject. The hormone was separated from the adrenal blood plasma by extraction with ethylene chloride. A 5% ethyl alcohol solution of the hormone was injected in 4 equal doses over an 8-hour period into adrenalectomized, 24-hour starved mice. The amount of liver glycogen deposited was an indicator of the gluconeogenic hormone present. Under the conditions of the experiment an appreciable amount of gluconeogenic hormone was always being secreted. Injection of ACTH increased the amount secreted per unit of time, but large amounts of epinephrine appeared to have little influence under experimental conditions.

Axon as model of synapse: new evidence of similarity of conduction and transmission THEODORE HOLMES BULLOCK *Dept of Zoology, Univ of California, Los Angeles*

Death of the all or none impulse at a predisposed locus and rebirth of a new impulse beyond (BLAIR AND ERLANGER, 1939, in frog fibers) was restudied in invertebrate fibers with 4-gun cathode ray tube. The necessary and sufficient condition is a lower curve of local response decrement with distance than of return of excitability. Two conditions that seemed necessary in the frog experiments are shown not to be essential: current eddies through nodes of Ranvier and a locus of artificially heightened excitability (cathode) within the critical distance (ca. 1 mm). Present results emphasize the importance of actively (though decrementally) propagated local response and the short distance over which crucial changes in excitability may occur. One-way conduction was directly shown in single fibers (cf BISHOP AND ERLANGER, 1926, ROSENBLUTH *et al*, 1949) with multichannel recording. Its locus is very restricted. It can occur without polarization and as a result of either static conditions or fluctuating conditions associated with immediately preceding impulses. After-discharge in fibers frequently takes the form of one-way initiation. The synapse-like character is emphasized by long and variable delays. One-way inhibition is a consequence. Excitability may locally change in discontinuous manner through several steps in rapid, erratic succession. It is apparently critical that immediately preceding impulses fol-

low a certain temporal and spatial pattern. The explanation seems to lie in local response properties. The result amounts to genuine integration and introduces long, variable local delays. Finally, a labile facilitation of conduction rate has been found in fresh preparations of earthworm giant fibers.

Influence of tetraethylammonium chloride on the circulatory responses to the Valsalva maneuver IVAN L BUNNELL, DAVID G GREENE AND WILLIAM W KUNZ (introduced by FRED R GRIFFITH, JR) *Depts of Physiology and Medicine, Univ of Buffalo School of Medicine and the Buffalo General Hospital, Buffalo, N Y*

The response of the arterial blood pressure to the Valsalva maneuver has been noted previously to be a useful indication of the completeness of autonomic blockade by various blocking agents. Normally, after intrathoracic tension is released, there is an immediate drop in arterial pressure, followed by a rise to a level higher than that which existed before the maneuver. This 'overshoot', a manifestation of increased vasoconstrictor activity, is abolished by autonomic blockade. The adaptive reflexes normally resulting from the maneuver produce not only changes in vasoconstrictor activity, but also changes in heart rate. The presence of the latter provides another indication of an actively functioning autonomic nervous system. In the present study, arterial blood pressure has been measured in unanesthetized human subjects with a Hathaway blood pressure recording system attached to an indwelling arterial needle. The influence of intravenous infusions of tetraethylammonium chloride for varying periods of time in abolishing both the 'overshoot' and the changes in heart rate will be described, and discussed with regard to the relative sensitivity of these 2 criteria of autonomic blockade.

X-ray observations on dogs following explosive decompression to 30 mm Hg BUFORD H BURCH* AND FRED A HITCHCOCK *Lab of Aviation Physiology, Ohio State Univ, Columbus*

A series of 12 dogs were explosively decompressed to a terminal pressure of 30 mm Hg and maintained at this pressure for 2 minutes. Chest x-rays were taken 2 to 5 seconds after the explosion and subsequently at 30-second intervals. Partial collapse of the lungs occurred in all dogs shortly after the reduction of the pressure. This collapse of the lungs is believed to be due to vaporization of the intrapleural fluid, producing a condition which we have called 'vapo-thorax'. When these dogs were returned to normal atmospheric pressure the lungs expanded, completely filling the thorax, indicating that there was no pneumothorax or rupture of the lungs. Vapor usually appeared in the right heart 30 seconds after the ex-

plosive decompression and in the left heart about one minute later Vapor is usually found in the right heart before it is noted elsewhere When vapor was present in the left heart the dog usually died Marked dilatation of the heart occurred in all dogs We believe that blocking of the coronaries by vapor is an important cause of death It is also possible that the presence of vapor in the right heart may, by producing circulatory vapor lock, be a significant factor in the precipitation of ventricular failure Two dogs survived In one there was no vapor visible by x-ray present in the heart The other surviving animal had considerable vapor in his right heart and showed cardiac dilatation which persisted for about a week

Permeability of the urinary bladder to radioactive phosphorus, mercury and gold L E BURGESS,* D T ROLFE,* P F HAIN AND E L CAROTHERS * *Dept of Physiology and Cancer Research Lab, Meharry Med College, Nashville, Tenn*

Female dogs weighing 8-15 kg were anesthetized by intravenous sodium pentobarbital The ureters were doubly ligated at the bladder, severed, and the proximal ends cannulated to collect the urine flow A catheter was introduced into the bladder and the latter was emptied and washed several times with a warmed physiological salt solution Two to 5 m μ of radioactive H_3PO_4 , $HgCl_2$ and colloidal Au in warm physiological salt solution were allowed to flow slowly through the catheter into the bladder Analyses for P^{32} , Hg^{203} and Au^{198} were made at hourly intervals for a period of 6 hours on samples of blood taken from the external jugular vein and on samples of urine simultaneously collected from both ureters The blood showed a marked uptake of P^{32} during the first hour which reached its peak between the fourth and fifth hours The uptake of Hg^{203} by the blood was found to be very low during the first hour but increased rapidly and reached its peak between the second and fourth hours By the end of the sixth hour, a considerable absorption of both phosphorus and mercury had occurred from the radioactive materials instilled into the bladder, as revealed by analyses of the blood The rate of excretion of P^{32} and Hg^{203} by the kidneys, as shown by analyses of the ureteral urine, increased with the rise in blood levels of P^{32} and Hg^{203} Work in progress appears to indicate some slight absorption of colloidal gold by the urinary bladder

A new view of relation between pressure and flow in a vascular bed, and validity of 'peripheral resistance' ALAN C BURTON, J T NICHOL,* F GIRLING,* AND WM JERRARD * *Dept of Biophysics, Univ of Western Ontario Med School, London, Ontario, Canada*

The non-linear relation between pressure and flow of blood in vascular beds has been variously

explained as due to the distensibility of the vessels, changing the resistance with the pressure and to the anomalous viscosity of blood, changing with the velocity of flow Neither of these is the important factor Physical theory and experiment show that the equilibrium of the small vessels is unstable If the pressure within them falls below a critical value, dependent of their size and on the tension in the wall, they close abruptly and completely At pressures well above this 'critical closing pressure,' direct observation shows that the small vessels act like almost rigid tubes Under vasomotor tone the critical closing pressure may be above 100 mm Hg (spasm) Experimentally obtained curves of resistance vs pressure show an almost constant resistance until the critical pressure is approached, when it rises quite abruptly to infinity The rise is more abrupt with Ringer's solution than with blood These results re-establish the usefulness, in haemodynamics, of the 'resistance' when combined with a knowledge of the 'critical closing pressure' and also give a new view of the nature of spasm

Bile cholesterol, bilirubin, and physical constants in the rat SANFORD O BYERS, MEYER FRIEDMAN AND FRED MICHAELIS * *Harold Brunn Inst, Mount Zion Hospital, San Francisco, Calif*

An external bile fistula was created in 23 albino rats by inserting a catheter of plastic tubing into the bile duct and externalizing the free end of the tubing through the abdominal wall Each animal was restrained by a special technique, allowed water or 0.8% saline *ad lib*, and the entire 24-hour biliary output collected for determination of cholesterol bilirubin and physical constants The average concentration of free cholesterol (substantially equivalent to total cholesterol) was 12.7 mg/100 cc the average 24-hour total output was 1.83 mg Bilirubin was produced in total quantity of 1.2 mg/24 hours (av 7 rats) The average volume of flow per 24 hours was approximately 15 ml, or 5 ml/100 grams body weight Secretory pressure was 22-24 cm of bile of average specific gravity 1.011 The pH (glass electrode) varied from 7.9 to 8.5, average 8.3

Human tolerance and responses to high positive pressure breathing CLARENCE C CAIN, JOHN A WOOD AND DAVID I MAHONEY (introduced by J W HEIM) *Aero Med Lab, Air Materiel Command, Wright-Patterson Air Force Base, Dayton, Ohio*

An experimental study was conducted to determine the time tolerance of a group of individuals breathing oxygen at various positive pressures from 30 to 60 mm Hg at room temperatures of 65°F and 95°F The heart rate, venous pressure, pulmonary ventilation and relative cardiac output as measured by the ballistocardiogram, were deter-

mined for certain pressures. The end point of these time tolerance studies was symptoms of impending syncope. A fairly narrow time range of tolerance occurred with the high pressures of 50 and 60 mm Hg. This range widened considerably at 30 and 40 mm Hg approximating time tolerances of 1 min at 60, 7 min at 50, and 15 min at 40 mm Hg. When breathing on 30 mm Hg pressure, the time was extended to between 1 and 2 hours and the exposures were terminated due to fatigue rather than impending syncope. However, at the same pressures at 50,000 feet it was necessary to terminate the exposures after 10 minutes on 2 subjects. At pressures of 40 mm Hg there occurred an average increase in heart rate of 50% and a reduction in cardiac output of approximately 42%. The venous pressure increased but not in linear relationship to the increase in mask pressure. These responses are in accord with the accepted view that impending syncope is due to circulatory stress. The pulmonary ventilation on a group of 7 subjects at ground level breathing oxygen at a positive pressure of 30 mm Hg increased to 150% of normal during the first 5 minutes and decreased to 130% of normal at the end of 20 minutes. The ventilation did not return to normal on any of the subjects tested while exposed to 30 mm Hg breathing pressure.

Relatively light doses of sesame oil on oxygen consumption and role of adrenal cortex THOMAS B. CALHOON* AND CLIFFORD A. ANGERER *Dept of Physiology, Ohio State Univ., Columbus*

We have previously reported (*Anat Rec Suppl* 105:142, 1949) the effects of large doses of sesame oil on the oxygen consumption of 'normal' goldfish and that these effects were antagonized by adrenocortical extract. Recent studies with light doses of sesame oil have shown that the previous results are open to a different interpretation. Oxygen consumption determinations were made weekly on 2 groups of goldfish over a period of 7 weeks, using a respirometer developed in this laboratory. All fish were fasted from 12-18 hours prior to use to render them in a 'basal' state. A group of 12 fish were given 1 ml 0.0002 cc sesame oil/gm of body weight/every other day for a 7-week period. At the end of the second week the mean metabolic rate increased 12% compared with controls. This was followed by a sharp drop in oxygen consumption until the 7th week when the mean value was 40% below normal. A second group of 12 fish were injected 1 ml with 0.0002 cc sesame oil and 0.00036 cc Upjohn's Adrenocortical Extract/gm body weight every other day for a 7-week period. At the end of the second week the mean oxygen consumption decreased 35% from normal. This was followed by a leveling of these values at ca -37%. Although the weights of all fish fluctuated greatly, the mean weight of fish given sesame oil alone increased 3%

at the end of the 7th week. Fish given adrenocortical extract plus sesame oil increased 26% at the end of this period.

Experimental analysis of electrical responses of inferior colliculus to sound and cutaneous sensibilities BERRY CAMPBELL *Dept of Anatomy, Univ of Minnesota Med School, Minneapolis*

Responses evoked in the inferior colliculus and associated structures by condenser discharges through a piezo-crystal near the ipsilateral or contralateral ears have been recorded by micro-electrodes using a cathode ray oscillograph. Additional data on the responses of these centers to spinal nerve stimulation is presented. Correlation of structure and electric potential of cell groups and tracts is made on the basis of histological examination of the needle tracts. Monkeys, cats, rabbits, and rats have been used in the experiments. The potential evoked by a contralateral click in the inferior colliculus consists of 2 components, one a pick-up from the underlying nucleus of the lateral lemniscus responding at 4 msec, and a local potential commencing at the base of the colliculus and rising at a speed of from 0.5 to 1.0 msec/sec to the dorsum. Analysis of the sign changes and spike form of this potential indicates that it is conducted as an upward rising positive-negative wave. The distribution of the potential of the lateral lemniscus shows that the cells, upon activation, form the center of a strong bipolar field, the dorsal side positive, the ventral negative. This potential is marked throughout the colliculus and the underlying tegmentum, but spiking, and the highest voltage is seen at the nucleus. Contralateral clicks evoke much less activity. Stimulation of contralateral spinal nerves evoke potentials in the inferior colliculus. These decrease the response of the inferior colliculus to auditory activation.

Flight response of drosophila to variations in temperature L. E. CHADWICK *Medical Div., Army Chemical Center, Md*

Data are presented to define the variations in wing-beat frequency of flies as a function of age and temperature.

Positive pulse stimulation of anterior sigmoid and precentral gyri: electric current threshold dependence on anesthesia, pulse duration, and repetition frequency WILLIAM W. CHAMBERS, GEORGE M. AUSTIN AND JOHN C. LILLY (introduced by MARGARET SUMMALT McCOUCH) *Dept of Anatomy, Neurosurgery and Biophysics, Univ of Pennsylvania, Philadelphia*

In determining current thresholds (J) for positive pulses (durations (PD) from 0.1 ms - 500 ms) at frequencies (PRF) from 1/60 to 9000 pulses/sec, trains (5 sec duration, 1/min) are sent through an

Ag-AgCl-saline pore electrode (10 mm diameter) on a cortical motor zone in 3 series of animals. For each stimulus the threshold current value and pulse waveform are determined by observation by means of a series resistor, a direct-coupled amplifier, and a cathode-ray oscilloscope. The animals' movements were observed by visual means. Exposed cortex and anesthesia (dial 4 mg/kg) were used in the first series (I) (5 cats and 3 monkeys), exposed cortex and none but local anesthesia in the second series (II) (2 monkeys), and a closed cranium and only local anesthesia in the third (III) (1 monkey). Horsley-Clark fixation was used in I, skull edge fixation in II and an implanted electrode in III.

The resulting curves of J versus PRF for constant PD were reproducible for several hours. In I and II the 'rheobase' was 1.1 ma at 10 ms at all PRFs, at 10 ms above 500 cps and at 0.1 ms above 1000 cps. A low PRF (1/60-15/sec) plateau (12 ma at 0.1 ms, 3-6 ma at 10 ms) is connected by a uniformly falling curve to the high PRF 'rheobase'. In contrast in III, on the 1st day, the low PRF plateau is connected to the high PRF plateau by a 'valley' (minimum at 10 ms, 200 cps and 0.65 ma, at 0.1 ms, 200 cps and 2.0 ma), in the 2nd through the 3rd day this curve changes from the valley-type to the I and II type. In the same animal, on other side, cutting out upper cortical layers caused immediate flattening of the valley. There was little if any impairment of voluntary use of responding part on either side at any time during 8 days of observation.

Influence of pulmonary proprioceptive reflexes during electrophrenic respiration. PAUL O. CHATFIELD* AND STANLEY J. SARNOFF *Depts of Physiology, Harvard Med School, and Harvard School of Public Health, Boston, Mass*

During periodic stimulation of a phrenic nerve to produce descent of the diaphragm (electrophrenic respiration), one obtains an inhibition of spontaneous respiration which is clinically useful since it eliminates the conflict between the patient's spontaneous breathing and the imposed respiration. It has been shown that this inhibition can be brought about by vagal reflexes alone or secondarily by hyperventilation. In the present study, by recording muscle action potentials from the left (unstimulated) leaf of the diaphragm and from inspiratory intercostal muscles in dogs during application of electrophrenic stimulation to the right phrenic nerve, it was possible to ascertain the conditions of electrophrenic respiration which facilitate the desired inhibition of spontaneous respiration. It was found that inhibition depends on the integrity of the vagi (previously shown), that inhibition of spontaneous respiration is facilitated by a) an increase in rate of electrophrenic

respiration, b) prolongation of inspiration and c) an increase in the depth of inspiration. A changed state of excitability of the respiratory center (as from rebreathing) may cause previously inhibited spontaneous respiratory discharge to resume. Under many conditions, even when spontaneous respiration was not completely inhibited, there was synchronization of spontaneous and electrophrenic respirations. The prompt suppression of spontaneous respiration seems much more easily obtained with an active diaphragmatic contraction than with positive pressure breathing. The results are discussed in the light of recent unitary analysis of pulmonary proprioceptors and their practical significance pointed out.

Studies on pharmacology of tetraethylthiuramdisulfide (Antabuse) and the 'Antabuse-Alcohol' syndrome in animals and man. GEORGE P. CHILD, EUGENE BARRERA,* WALTER OSINSKI,* ZACK RUSS* AND GEORGE HEMSTED* *Depts of Physiology and Pharmacology, Neurology and Psychiatry, and Medicine, Albany Med College, Albany, N Y*

The duration to alcohol sensitization by Antabuse was tested in rats. The sensitization reached a maximum 6-12 hours after giving an oral dose of Antabuse and it lasted for 10-15 days. The duration and degree of effect were determined largely by the dose of Antabuse given. The ascending paralysis produced by large doses of Antabuse in animals could not be alleviated by prostigmine and was suggestive of the paralysis caused by spinal cord interneuron blocking drugs. This was tested by giving white rats convulsant doses of strychnine. The Antabuse did not protect the rats from the cord stimulating effect of strychnine. Humans who are under treatment for chronic alcoholism were given a test dose of alcohol before and after the administration of Antabuse was started. Among the signs and symptoms of the Alcohol-Antabuse syndrome are hypotension, tachycardia, hyperpnea, ECG changes, descending erythema, feeling of warmth, diaphoresis, thirst, gastric hypermotility, nausea, confusion, blurred vision, vertigo, and above all the amazement on the part of the patient that such minute amounts of an alcoholic beverage can make one feel so peculiarly. The temporal and intensity relations of these effects will be presented. At present the best antidote for this syndrome is intravenous ascorbic acid. The effect of Antabuse alone is discussed.

Use of intravenous ethanol in treatment of a case of opiate addiction, and other experimental therapeutic tests with intravenous ethanol in humans. GEORGE P. CHILD, FRANK CLARE* AND JOHN FARRELL* *Depts of Physiology and Phar-*

macology, Neurosurgery, and Surgery, Albany Med College, Albany, N Y

The pharmacologic properties of intravenous ethanol as an analgesic, euphoric antipyretic and vasodilator have been used by us with good effect in the treatment of phantom limb pain, peripheral vascular disease (to test the ability of the vessels to dilate), pyrexia and in the management of intractable patients. Another use, which deserves particular emphasis because of its significance if verified by further work, is in the treatment of opiate addiction. Three patients have, thus far, been under treatment. Two of the patients had very painful lesions and were receiving a considerable quantity of opiate. During the period of alcohol administration it was possible to reduce the opiates and even eliminate them for a day or two without producing withdrawal symptoms. Because of the lesions, however, it was felt that the opiates should not be withheld. The other patient had been receiving natural and synthetic opiates for approximately 3 years. After surgical treatment for her lesion, attempts were made to cure her of addiction without success. She also had diabetes and hyperthyroidism. When the 5% intravenous alcohol (Abbott) was started all opiates were discontinued. On each of 6 successive days she was given from 1- $\frac{1}{2}$ l of 5% alcohol in divided doses with a complete cure of addiction. The only withdrawal effects noted were mydriasis, mild diarrhea and a pyrexia of 101° for one day. Although this one case has thus been cured of addiction the result was so spectacular as to warrant publication.

Effect of depletion of extracellular electrolytes on the water intake in dogs LOUIS J CIZEK,* ROBERT E SEMPLE,* K C HUANG* AND MAGNUS I GREGERSEN *Dept of Physiology, College of Physicians and Surgeons, Columbia Univ, New York City*

The experiments were designed to test whether or not the degree of cellular hydration determines the fluid intake. Following a 2- to 3-week control period during which observations were made on levels of serum chloride, plasma protein, plasma volume, thiocyanate space, water intake and output, the animals were depleted of extracellular chloride and sodium by the intraperitoneal glucose procedure. The dogs were then maintained on a low salt diet for a period of one to 3 weeks, throughout which the serum chloride, plasma volume and thiocyanate space remained at low levels. The dogs were lethargic immediately after the salt depletion but this lethargy wore off gradually in a day or two. Within 48 hours the water intake exceeded the control intake. Urine excretion likewise increased. The increase in water intake varied from 33 to 85%. One dog, however, refused to eat

after salt depletion. Nevertheless his fluid intake and urine output were greater than when the same animal in normal electrolyte balance was placed on a starvation regime. With intravenous sodium chloride and restitution of salt to the diet, water intake, plasma volume, plasma protein etc returned to control levels. These findings are not in accord with the concept that the degree of cellular hydration determines the fluid intake.

Thalamic loci of afferent stimulation in the cat SYDNEY M COHEN (introduced by FRED A METTLER) *Dept of Neurology, College of Physicians and Surgeons, Columbia Univ, New York City*

Upon electrical stimulation of afferent nerves (face, limbs) or tactile stimulation of skin, electrical activity (50-200 uv, 5-40 msec duration) is recorded with needle microelectrodes in the ventral posterior thalamic nucleus. The responses to face afferent activity have the shortest duration. Contralateral stimuli produce greater activity than do ipsilateral. Only forelimb stimulation elicits activity in a small region of the rostro-medial part of the nucleus. Elsewhere, activity is elicited by afferents from hind- and forelimbs or face, though the responses differ in amplitude and duration. Potentials referable to pick-up of incoming activity are observed over a wider region of the thalamus. Cervical section of lateral columns does not affect thalamic activity, but section of dorsal columns abolishes thalamic responses to limb afferent impulses. Electrical stimulation of one nucleus produces no response in the other. Nor does division of anterior, middle or posterior commissures alter responses of either nucleus. Cross connections between nuclei are therefore lacking. Latency of thalamic response remains nearly constant with increasing afferent stimuli. However, the time difference between arrival of afferent activity in the nuclei of the dorsal columns and the onset of the thalamic response is 10-20 msec greater for the forelimb activity than for that of hindlimbs.

Effect of intraluminal hydrostatic pressure on water and sodium movement across intestinal wall of dogs S T COLEMAN, R F JONES AND M J FOGELMAN (introduced by ROBERT W LACEY) *Dept of Exper Surgery, Southwestern Med School of The Univ of Texas, Dallas*

In an attempt to determine the causes for the collection of fluid in an obstructed intestine the effects of various intraluminal pressures on water and sodium exchange were studied in Thiry-Vella loops of trained unanesthetized dogs. Forty ml of a 1% aqueous solution of D₂O were placed into the Thiry-Vella loops and subjected to maintained pressures of 10, 20, 30 and 40 cm of water for 90 minutes. Samples for Na and D₂O determinations

were withdrawn by catheter from the lumen at graded intervals. The heavy water analyses were made by the falling drop method and the sodium determinations by flame photometry. At the termination of the experiments the gut was emptied with a catheter and the remaining volume measured. The rates of movement of water into and out of the intestine were calculated by the method of Visscher (*Am J Physiol* 142: 550, 1944). There was no positive correlation between the intraluminal hydrostatic pressures and the rates of movement of water and sodium across the intestinal wall. Eleven additional experiments using a constant initial volume of plain water and pressures varying from 10–40 cm of water also failed to show a correlation between intraluminal pressure and net rate of movement of water across the intestinal wall.

Effect of X-irradiation on intestinal motility

ROBERT A. CONARD (introduced by HARVEY M. PATT) *Biological Div., Argonne National Laboratory, Chicago, Ill.*

In vivo studies have been carried out measuring kymographically contractions of the longitudinal muscle of rat jejunum immersed in constant temperature Tyrode's solution. During X-irradiation with doses of 100 r (250 kv, 100 r/min), and above there is a typical pattern of intestinal activity produced. After a lag of about one minute there is an increase in tone accompanied by an augmentation of contraction which continues for several minutes after the irradiation is terminated. Tonus gradually returns to the pre-irradiation level (with 100 r in about 4–6 minutes). Larger doses of irradiation in general produce a higher and longer rise of tone. Shielding studies and *in vitro* irradiation of isolated segments of intestine reveal that the contraction response is largely due to a direct effect on the intestinal tract. Atropine and nicotine strongly inhibit the response while physostigmine augments and prolongs it. Sympathetic drugs have little or no effect. Immediate vagotomy has no appreciable influence while vagotomy of a week's duration gives an augmented response to x-ray. The antihistaminic benadryl has no effect. These data suggest that the x-ray response is largely due to a direct effect on the intestinal tract, specifically, on its parasympathetic elements.

Bicarbonate concentration of pancreatic juice during experimental acidosis

S. S. CONLY,* J. O. CRIDER AND J. E. THOMAS *Dept. of Physiology, Jefferson Med. College, Philadelphia, Pa.*

Unanesthetized dogs with permanent gastric and duodenal fistulas fitted with metal tubes were used, and the pancreatic juice collected during intravenous administration of secretin. The normal curve of bicarbonate secretion was determined for

each animal. The concentration of bicarbonate was plotted on the ordinate and the rate of secretion on the abscissa. With rapid rates of secretion the bicarbonate concentration appears to approach a maximum asymptotically. Acidosis was produced by the intragastric administration of 500 cc of a 2% ammonium chloride solution through the gastric fistula at a rate of about 125 cc/hr. Two or 3 days of such administration lowered the CO_2 combining power of the blood plasma from a normal of 22–24 mm/l to 12–16 mm/l. The bicarbonate content of pancreatic juice as evoked by secretin was determined for 2 or 3 days following the administration of ammonium chloride. After this time the blood CO_2 had returned to normal and the bicarbonate of the pancreatic juice to normal. During the period when the blood CO_2 was lowered the CO_2 content of the pancreatic juice was lowered for a given rate of secretion but the curve has the same general form as before the period of acidosis. The bicarbonate content of the juice for a given rate of secretion was lower the second day than it was on the first day following the administration of the ammonium chloride and this at a time when the blood CO_2 was approaching its former normal level.

Effect of electrical polarization on oxygen consumption of nerve

CLARENCE M. CONNELLY* AND DETLEV W. BRONK *Dept. of Biophysics, Johns Hopkins Univ., Baltimore, Md.*

It is well known that the membrane potential of resting nerve is maintained by oxidative metabolism. However, little or no information exists with respect to the effect on the oxygen consumption of nerve of an imposed electrical polarization. An attempt has been made to determine the degree of interaction between the mechanism maintaining the membrane potential of frog nerve and the reaction system that consumes oxygen. Two types of experiment have been performed, using a polarized platinum electrode in contact with the nerve to determine changes in the rate of oxygen utilization. In the first type of experiment, anodal or cathodal polarization was applied to a resting nerve in the region of the oxygen-recording platinum electrode. The changes in the rate of oxygen utilization resulting from polarization (0.25–2.0 microamperes, 1–10 minutes) were strikingly small, being considerably smaller than, or at most of the order of, 1% of the resting rate. The sensitivity of the measuring system was in this case determined in terms of the steady-state extra-oxygen consumption resulting from 1 impulse/sec. In the second type of experiment, the region of nerve immediate to the oxygen electrode was blocked with excess potassium ion. During a period in which local anodal repolarization of the nerve relieved the block, it was found that the conduc-

tion of impulses (100/sec, 50 sec) did not result in detectable extra-oxygen consumption

Influence of diet composition on alarm reaction to acute stress P. CONSTANTINIDIS (introduced by H. SELYE) *Institut de Medicine et Chirurgie experimentales Université de Montreal, Montreal, Canada*

Rats gavaged with isocaloric and isovitaminic amounts of high-amino-acid and high-carbohydrate diets were exposed to various types of acute sublethal stressors (cold, muscular exercise, formaline, urethane, colchicine) for short periods of time. It was found that in every instance the dietary intake significantly modified the ensuing alarm reaction. Thus, in the case of every stressing agent except colchicine, adrenal enlargement, cortical lipid discharge and lymphatic karyoclasia were maximal on a high-amino-acid and minimal on a high-carbohydrate intake. The response to colchicine was conditioned in the reverse fashion. Chemical estimations of adrenal cholesterol, adrenal ascorbic acid and liver glycogen were subsequently performed in animals exposed to cold for 1, 6, 15 and 30 hours. During the first 15 hours the rats fed a high-amino-acid diet showed a considerably greater cholesterol and glycogen depletion than those on a high-carbohydrate diet, while at 30 hours of cold the difference between the 2 nutritional groups decreased. There was no difference in the ascorbic acid response between groups at any interval. The influence of protein on the pituitary-adrenal system under resting conditions has remained controversial up to date. It has been shown by Selye (*J Clin Endocrinol* 6:117, 1946) however, that high protein diets aggravate certain pathological changes provoked by prolonged exposure to stress or anterior pituitary principles. The present data demonstrate that the adrenal response to acute, short-lasting stress is also conditioned by the amount of protein or carbohydrate in the diet.

Observations on the etiology of explosive decompression injury E. L. COREY AND E. G. LEWIS * *Univ. of Virginia Med. School, Charlottesville*

The explosive (0.64 sec) decompression of rats (250) to 21 mm Hg was found to be innocuous even when frequently repeated (20 exposures), provided recompression was immediate (> 1 sec). Mortality was observed to be directly related to post-decompression time under reduced pressure, and all rats succumbed when this interval was prolonged to 40 seconds. Animals placed in an atmosphere of nitrogen succumbed within a comparable period (63.5 sec). However, such procedures as pre-oxygenation and resuscitative measures (insufflation with air, O₂, CO₂, O₂-CO₂) failed to produce striking reductions (av. 25%) in mortality. Aeroembolism was never observed within the vessels (jugular,

mesenteric, renal, femoral) of animals under 21 mm Hg, although present *in vitro* in rat blood at this pressure. Alterations in autonomic activity (vagotomy, atropine, mecholyl) reduced mortality only 22%. Hence aeroembolism and endogenous autonomic activity appeared to represent minor determinant factors. On the other hand, anesthetics (cold, ether, evipal, pentothal) enabled all animals tested (29) to survive the normally lethal time-interval under reduced pressure. Indeed this period might be lengthened by as much as 100% without fatality in anesthetized rats. It was noted that the convulsive dyspnea characteristic of normal animals under such conditions was absent. On the basis of these experiments it was considered that intrapulmonary gas expansion *per se*, aeroembolism, and endogenous autonomic nervous influences do not constitute primary etiologic agents in explosive decompression injury, but that anoxic anoxia, with resultant convulsive dyspnea, represents the major factors producing lethal injury under the conditions cited.

Diuretic effects of sodium salts of organic acids in patients with cardiac and nephrotic edema

SAMUEL A. CORSON, ELIZABETH O'LEARY,* MITCHELL W. SPELLMAN,* ABRAHAM L. SIEGEL,* AND LESTER HARRISON * *Dept. of Physiology, Toledo Hospital Inst. of Med. Research, Toledo, Ohio*

Following a period of bed rest, a 1.4 M solution of disodium succinate-fumarate was infused intravenously to a patient with cardiac edema at the rate of 1.3 ml/min, giving a total dose of 2.8 ml/kg body wt. This led to a diuresis of 12.9 ml/min (average) for a period of 325 minutes (control = 1.3 ml/min). The total volume of urine during this period was 4.2 l. The next day the patient showed no pitting edema. The thiocyanate space was reduced from 27 l (34.5% of body wt) to 19 l (25% of B.W.). The patient remained edema-free for the duration of her hospital stay (one week). The rate of Cl and Na excretion increased parallel with the diuresis. During the 325 minutes the patient excreted 275 mEq Cl (2.2 mEq infused) and 708 mEq Na (635 mEq infused). A similar infusion was given to a patient with longstanding rheumatic heart disease and terminal renal insufficiency (probably of obstructive origin) exhibiting progressive oliguria, uremia, ascites and pitting edema limited chiefly to the lower extremities. A diuresis of about 3 l was obtained without significant improvement in the clinical condition. Two infusions to one nephrotic patient with hypoproteinemia, severe ascites and pitting edema led to a diuresis of 4 l for a period of about 400 minutes both times. At the end of both experimental periods the patient showed Na retention. Another nephrotic patient failed to give any diuretic response. This patient proved to have depressed

clearances of inulin and para-amino hippurate. More detailed studies are in progress.

Relation between heat balance and physiological strain in walking men clad in a ventilated impermeable envelope F N CRAIG *Medical Div , Army Chemical Center, Md*

Measurements of metabolic heat production and of heat removed by ventilation were made on men enclosed in an impermeable garment and walking on a level treadmill at 3 miles/hr in a room at 85° F. Ventilating air was introduced at the 4 extremities and the top of the head by means of an internal manifold, and left through an opening at the waist. The heat removed was calculated from increase in temperature and moisture content of the ventilating air. Inspired and expired air were kept separate from the ventilating air with a gas mask. Metabolism was determined by analysis of expired air. Heat balance was altered by varying the flow rate, temperature and moisture content of the ventilating air. The physiological strain was measured in terms of an index obtained by adding sweat production in kg/hr, the rise in rectal temperature in degrees C/hour, and one hundredth the heart rate at the end of a 30-minute period. In 28 tests the physiological index ranged from 2-5. The heat stress, defined as the metabolic rate in calories/hour minus the heat removed by ventilation, ranged up to 300 calories/hour. The index increased at the rate of one unit of strain ± 0.5 unit/100 calories of heat stress. This formulation provides a measure of heat stress free of a heat storage term depending on body temperature measurements, and so permits their use in an index of strain.

Some effects of oxine, carbostyryl and quinoline on isolated, living bullfrog nerves FREDERICK CRESCITELLI *Dept of Zoology, Univ of California, Los Angeles*

The role of metal-containing enzyme systems in numerous cellular reactions is recognized. Such enzyme systems may be inhibited by agents which combine with the metal. To test for the possible participation of a metal-enzyme system in the mechanisms which maintain the nerve resting potential and in the reactions which determine impulse conduction, the effects of 8-hydroxyquinoline (oxine) on bullfrog nerve have been examined. Oxine is a powerful chelating agent for a number of metals. When a 0.003M solution of oxine in Ringer fluid is added to a segment of nerve, block of the A fibers occurs in about 30 minutes. This block is reversible if the nerve segment is washed promptly, but if exposure to the oxine is continued for 10 or more minutes, restoration of conduction is incomplete or absent. In addition, oxine produces an elevation in the nerve resting potential of about 0.5 mv. It is

doubtful, however, whether either of these effects can be attributed to interference with a metal-enzyme within the nerve. This conclusion is based on the fact that 2-hydroxyquinoline (carbostyryl) and quinoline, both poor metal chelators, are also capable of producing nerve block, although concentrations of 0.006-0.008M are required. Moreover, quinoline is also capable of eliciting slight positivity. Carbostyryl has no measurable effect on the resting potential. The similarity of action of all 3 substances, only one of which is a good chelator, suggests some mode of attack other than through a metal-enzyme system.

Depression of capillary responses to epinephrine by ferrous iron J M CRISMON *Dept of Physiology, Stanford Univ , Stanford, Calif*

Mazur and Shorr identified the hepatic vasotropic factor (VDM) as ferritin (*J Biol Chem* 176:771, 1948). They attributed its action to the protein rather than the iron because injection of apoferritin depressed terminal vascular response to epinephrine as effectively as ferritin. Laurell (*Acta Physiol Scand* 40 Supp 46, 1947) reports plasma Fe globulin up to 250 μ g Fe/liter. This could furnish Fe in sufficient amount to permit injected apoferritin to reach terminal vascular smooth muscle as ferritin. The action of Fe on epinephrine sensitivity was tested on the Zweifach rat mesoappendix preparation by injecting FeSO_4 in doses calculated to saturate iron-carrying globulins in plasma. Intravenous Fe^{++} in doses of 91 μ g/kg raised the epinephrine threshold of the capillary bed in exteriorized rat mesoappendix 3- to 15-fold, a response greater than that obtained by 0.5 ml doses i.v. of saline extract of anaerobic liver or of edema fluid from rat legs after release of 4-hour tourniquets. Thus, Fe^{++} produced vaso-depression without added specific protein. The depressed responses in the vessels of the rat mesoappendix produced by Fe^{++} and by vasodepressor material from ischemic liver and muscle were both reversed by intravenous injections of rutin in propylene glycol in doses of 2 mg/kg, but rutin exposed to metallic iron lost its ability to increase capillary sensitivity to epinephrine. The increased sensitivity to epinephrine after rutin may depend upon competition of rutin with epinephrine destroying enzymes for Fe^{++} (WELCH, A D *Am J Physiol* 108:360, 1934).

Pathogenesis of plasma transfusion reaction WILLIAM H CROSBY AND MARIO STEFANINI (introduced by DAVID RAPPORT) *Ziskind Labs (Hematology section) of the Joseph H Pratt and New England Center Hospitals and the Dept of Medicine, Tufts College Med School, Boston, Mass*

Certain patients develop febrile reactions following transfusion of compatible whole blood. These reactions occur after plasma transfusion

but not after washed red cells (Dameshek, W and J Never In press) Patients with paroxysmal nocturnal hemoglobinuria, in addition to chill and fever, also develop a hemolytic crisis Since the hemolytic factor in paroxysmal nocturnal hemoglobinuria is probably identical with a coagulation accelerator, (Crosby, W II and W Dameshek In press) it was suspected that the plasma transfusion reaction involves the clotting mechanism The behavior of the known clotting factors was studied during such reactions 1) The platelet count fell sharply just preceding the chill 2) Clotting time became shorter Clot retraction became incomplete 3) Prothrombin activity was slightly decreased (70%) after the reaction 4) Prothrombin consumption increased at the time of the chill, thereafter slightly decreased 5) Serum coagulation accelerator activity diminished sharply during the reaction but thereafter increased above the original value At this point, in patients with paroxysmal nocturnal hemoglobinuria, the hemolytic reaction began 6) Plasma labile factor was increased (135%) at the time of the reaction Serum labile factor varied inversely with the accelerator activity 7) Fibrinogen was halved during the reaction 8) Fibrinolytic activity became intense The fibrin in clotted whole blood disappeared in an hour Fibrinolytic activity appeared with the first subjective evidence of reaction, reached a peak one hour after the chill and 3 hours later disappeared Plasma transfusion reaction involves a severe disturbance of the equilibrium of the coagulation mechanism The precipitating cause of the reaction has not been established The drop in platelets suggests that the clinical symptoms may be due to platelet embolism

Renal hemodynamic effects of Neosynephrine in man ARCHER P CROSBY, JR, JOHN KAPP CLARK AND HAROLD G BARKER (introduced by JAMES E ECKENHOFF) *William Pepper Lab, Dept of Medicine and Harrison Dept of Research Surgery, Univ of Pennsylvania Hospital and School of Medicine, Philadelphia*

The clinical observation of oliguria in several postoperative patients treated with Neosynephrine for the maintenance of blood pressure following hypotensive states led to measurements of renal plasma flow (PAH clearance), glomerular filtration rate (endogenous creatinine clearance), urine flow, blood pressure (direct arterial) and pulse rate in 5 normal subjects before and after the intravenous administration of 3-5 mg of Neosynephrine HCl Uniformly in all 5 patients blood pressure rose, pulse was slowed, renal blood flow was decreased and glomerular filtration and urinary output were essentially unchanged These data indicate that Neosynephrine results in renal

vasoconstriction, located chiefly in the efferent arteriole, with an increase in renal peripheral resistance greater than that of the body as a whole and a resultant shunting of blood away from the kidney to other vascular beds Although no change in urinary volume was demonstrated in these normal individuals, in shock, where decreased renal blood flow may be a primary factor in causing oliguria, this drug may delay recovery of renal function

Cerebral blood flow and oxygen metabolism following head-up tilt in hypertensive patients after sympathectomy CHARLES W CRUMPTON, JOHN H MOYER, HERBERT WENDEL, HENRY A SHENKIN, WILLIAM A JEFFERS AND JOSEPH H HAFKENSCHIEL (introduced by H S WIGODSKI) *Robinetle Foundation, Med Clinic, Hospital of the Univ of Pennsylvania, Harrison Dept of Surgical Research, and Dept of Pharmacology, Med School, Univ of Pennsylvania, Philadelphia*

Cerebral blood flow and oxygen uptake were measured in 14 post-sympathectomy patients, before and 20 minutes after 20° head-up tilt in order to evaluate the role of sympathectomy in the effects of semi-erect posture on the cerebral circulation of patients with primary hypertension The mean responses of the patients studied 3 weeks to 2 years after bilateral thoracolumbar sympathectomy were compared with data obtained similarly in 5 normotensive and 16 unoperated hypertensive patients Mean effective cerebral arterial pressure and cerebral vascular resistance were reduced with tilt after sympathectomy Cerebral blood flow was unchanged The oxygen content of the internal jugular venous blood was reduced and cerebral arteriovenous oxygen difference increased Cerebral oxygen uptake increased but not significantly ($p = 0.06$) The other changes were significant ($p < 0.02$) A greater mean decrease in effective cerebral arterial pressure during tilt was noted in the post-sympathectomy patients as compared with the normotensive and hypertensive group response The post-sympathectomy patients appeared to differ in respect to cerebral blood flow with tilt, showing a decrease, whereas a majority of normotensives showed an increase Otherwise, the data showed no evidence that the post-sympathectomy group of patients differed from the unoperated hypertensive group in the cerebral hemodynamic and metabolic adjustment to the 20° head-up tilt

Action potential of the Purkinje tissue of the ox heart HOWARD J CURTIS AND DAVID TRAVIS * *Dept of Physiology, Vanderbilt Univ Med School, Nashville, Tenn*

Certain of the false tendons of the ox heart are composed of strands of Purkinje cells surrounded by a thick layer of connective tissue. Histologically the cells appear to be separate from each other, but the myofibrils appear to be continuous from one cell to the next. These strands were dissected out at a local slaughter house a few minutes after the death of the animal, placed in ice Ringer's fluid, and taken to the laboratory. On warming, they seemed to be in excellent condition. These strands exhibit an injury potential of several millivolts. In recording between a killed end and an active region it is found that on stimulation the injury potential falls approximately to zero and stays there for some time and then suddenly recovers. In spite of the fact that histologically there appear to be a number of strands of cells in each bundle, the response is almost invariably all or-none. The action potential recorded between two electrodes on active tissue consists of a monophasic response followed by a T wave. It is concluded that the Purkinje system of the heart is a functional syncytium, and that physiologically Purkinje tissue is qualitatively identical to cardiac muscle.

Factors affecting acid secretion and cytological structure of mouse stomachs incubated *in vitro*

HORACE W. DAVENPORT, GOTTLIEB L. SCHNEEBELI* AND VIRGINIA J. CHAVRÉ* *Depts of Physiology and Anatomy, Univ of Utah College of Medicine, Salt Lake City*

Conditions have been found which greatly increase the rate of acid secretion by mouse stomachs *in vitro*. The conditions include incubation for one hour at 3200 mm Hg pO₂ and distention of the stomach to 75 cm H₂O. Optimal concentration of glucose is 15-30 mM/l, and lactate or pyruvate partially replaces glucose as an adequate substrate. No other adequate substrates have been found. Secretion occurs without extrinsic stimulation, but it is further increased by carbaminoylcholine or histamine. The optimal concentration of carbaminoylcholine is 0.1 mg %, and higher concentrations inhibit secretion. CO₂ in addition to that produced by the stomach is unnecessary. The cytoarchitecture of all cellular elements of the stomach is perfectly preserved, and the parietal cells are much larger and more granular than those in unincubated stomachs. Parietal cells of unincubated stomachs when stained with hematoxylin and eosin do not appear to contain canaliculi, but the parietal cells of stomachs secreting *in vitro* under optimal conditions contain large canaliculi which can be seen to envelope the nuclei of the cells and lead to the lumina of the glands. The frequency of occurrence and size of the canaliculi are directly correlated with the rate of acid secretion.

Effect of chronic underfeeding upon electrolyte concentrations of the plasma, brain and muscle of rats VIRGINIA D. DAVENPORT (introduced by LOUIS S. GOODMAN) *Dept of Physiology, Univ of Utah College of Medicine, Salt Lake City*

Plasma, brain and fat-free muscle of rats have been analyzed for sodium, potassium, chloride and water. The rats have been fed a standard diet *ad lib*, or they have been fed restricted amounts of the standard diet or synthetic diets high or low in sodium. Rats underfed with the synthetic diet high in sodium received the same quantity of sodium as those eating the standard diet *ad lib*. In all instances, regardless of the sodium intake, the plasma sodium concentration of underfed rats rose from a control level of 142 mEq/kg to a maximum of about 148 mEq/kg. The plasma chloride concentration rose concomitantly, but there were no changes in the plasma potassium or water concentrations. The sodium and chloride concentrations of the muscles of chronically underfed rats increased, the potassium decreased, and there was no change in the water content. However, the muscle sodium concentration of rats chronically underfed the low-sodium diet fell below the control level despite the fact that the plasma sodium concentration was high. Changes occurring in the brain electrolytes were smaller in magnitude. With the exception of those in rats underfed the low-sodium diet they were also opposite in direction.

Ninhydrin reaction with amines DEAN F. DAVIES* AND HENRY A. SCHROEDER *Hypertension Division, Dept of Internal Medicine, and the Oscar Johnson Inst, Washington Univ School of Medicine, St Louis, Mo*

Of the various theories regarding the humoral factors in hypertension, one with some experimental basis involves the production of pressor amines by an ischemic kidney. Investigation of this theory has been limited because of inadequate analytical techniques for identification of pressor amines in biological fluids. The present study deals with the techniques and results obtained in the first parts of a project designed to study amine metabolism in normal and hypertensive subjects. The reaction of ninhydrin with amines has been recognized for 35 years but has not been used. Four approaches are being made: 1) Spectral absorption characteristics of the reaction between amines and ninhydrin, 2) separation of amines from amino acids in blood and urine, 3) isolation and identification of naturally occurring amines, and 4) quantitative estimation of plasma amine concentrations in normal and hypertensive subjects. Spectral absorption curves have been obtained for the reaction between ninhydrin and methylamine, isoamylamine, arterenol, trypt

amine, tyramine, phenylethylamine, ethylamine, butylamine and histamine. Each of these compounds gave 2 peaks of maximal absorption, one ranging between 400 and 420 m μ , the second from 560-600 m μ . All amines had approximately the same limits (0.04-0.12 mv) of spectrophotometric determination between which standard curves were essentially straight. Guanine, guanidine hydroxylamine, epinephrine and choline gave no color. Since amino acids give a color with ninhydrin, extraction methods for quantitative separation of the bases from the acids are being studied and identification of individual amines by paper chromatography will follow.

Effect of high potassium on respiration and demarcation potential of a small locally-perfused area of cerebral cortex. P. W. DAVIES AND R. G. GRENNELL. *Dept. of Biophysics, Johns Hopkins Univ., and the Psychiatric Inst., Univ. of Maryland, Baltimore.*

Using the technique of local perfusion, combined with an occlusion-type oxygen electrode, described 2 years ago at these meetings, the oxygen consumption of a small area (approx. 2 mm diam.) of the cat's cerebral cortex has been measured. With the aid of a capillary pipette electrode the demarcation potential of the region has also been observed. The perfusion media were modified Krebs solutions containing Knox gelatine, glucose, bicarbonate buffer, but no phosphate. The standard solution, with all the ions in their normal concentrations, was capable of maintaining normal oxygen consumption and brain wave activity of the perfused area for about 2 hours, after which, especially if the perfusion pressure was high, local edema made measurements of oxygen consumption by the occlusion technique rather difficult. The colloid osmotic agent is essential in keeping respiration up (Grenell and Davies, this meeting). Solutions high in potassium were made up by replacing a corresponding amount of NaCl. Upon perfusing with high potassium (142 mM) the rate of oxygen consumption rises, reaches a level more than twice the normal value, and then declines to an approximately normal level in about 10 minutes after starting the perfusion. During this time the demarcation potential of the area falls uniformly and rapidly, reaching an asymptotic level about 10 mv below that of a distant unperfused cortical point. Curves showing the behavior at other concentrations of potassium are given. For example, when the potassium concentration is 50 mM, the respiration rises to an intermediate level, but tends to maintain itself there.

Auditory action potentials in response to clicks. H. DAVIS, C. FERNANDEZ* AND D. R.

McAULIFFE* *Central Inst. for the Deaf, St. Louis, Mo.*

Acoustic transients were produced by passing square or exponentially rising electrical pulses through a PDR-10 receiver. They were delivered to the ear of a guinea pig through a closed coupler that included a 62 mm length of plastic tubing. Strongly damped trains of waves at frequencies of 300, 2500 and 8000 cps could be identified in the aural microphonic. These frequencies correspond to peaks in the frequency response of the receiver and coupler. The pattern of action potentials was complex, but was nearly the same from holes in different turns of the cochlea. Three groups of nerve impulses correspond to the 3 frequencies mentioned. One or another could be largely suppressed by 1) local injury or electro-coagulation at the appropriate turn, or 2) by slowing the rise of the electrical wave (eliminating the 8000 cps wave), or 3) reducing the intensity (eliminating the 300 cps wave). At moderate intensity if the initial wave of the transient was rarefaction the several waves of action potentials (disregarding the late waves that apparently arise in the cochlear nucleus) were nearly synchronous, in condensation they were less synchronous and the latencies were in general longer, particularly for the 300 cps group. The method offers opportunity for measuring the latency of response of the cell bodies of the primary neurons (where these potentials apparently arise) as a function of intensity, polarity and wave form of the 'click'. Preliminary results will be presented.

Method for rapid measurement of intrarenal and other tissue pressures. JOHN C. DAVIS, JR.* AND H. G. SWANN. *Dept. of Physiology, Univ. of Texas School of Medicine, Galveston.*

Tissue pressures are measured by thrusting into the tissue a 20-gauge needle having several holes bored in its shaft. The needle is connected with a device for recording pressure, 250 mm Hg of pressure is then suddenly imposed upon the system. The elasticity of the pressure device then rapidly forces a small amount of saline-heparin (about 10 cm.) into the tissue until equilibrium is reached with the pressure of fluids in the tissue. The point of equilibrium is recorded, thus giving an objective measure of tissue pressures. The final equilibrium depends neither upon the volume of fluid forced into the tissue nor upon the pressure initially imposed upon the fluids in the needle. The results obtained by this method agree closely with those found by other observers for intramuscular and subcutaneous pressures. The intrarenal pressure, as measured in the renal medulla, was ascertained in studies on dogs under sodium pentobarbital anesthesia or after decerebration or in unanesthetized dogs with an ex-

planted kidney and contralateral nephrectomy. The pressure was found to average about 25 mm Hg and to range from 10-58 mm.

Effects of growth hormone on insulin hypersensitivity and glucose tolerance of hypophysectomized dogs R C DE BODO, M KURTZ,* A ANCOWITZ* AND S P KIANG * *Dept of Pharmacology, New York Univ College of Medicine, New York City*

Previous work has shown (*Federation Proc* 8 32, 1949) that while a potent adrenal cortical extract in massive doses exerted a marked 'anti-insulin' action in hypophysectomized dogs, the characteristic insulin response seen in normal dogs was never obtained. Therefore we investigated the possibility that lack of one of the anterior pituitary hormones might be at least partly responsible for the insulin hypersensitivity of hypophysectomized dogs. A purified preparation of growth hormone (Armour) was administered, 1 mg/kg daily, to hypophysectomized dogs manifesting a maximal insulin hypersensitivity (more than 60 times normal). Two doses of growth hormone, given in an 18-hour period preceding the insulin experiment resulted in a very marked 'anti-insulin' action, in that the blood sugar fell only slightly but after 4 hours it still had not returned to its pre-injection level. After daily administration of growth hormone for several days the exaggerated insulin response disappeared completely and the hypophysectomized dogs were even more resistant than normals when very large doses of insulin were used. In addition to insulin resistance, the hypophysectomized dogs treated with growth hormone had abnormally high post-absorptive blood sugar levels and diabetic glucose tolerance curves. Neither glycosuria nor acetoneuria was noted. A marked lipemia was observed. The dogs show a very rapid increase in weight although their food allotment was not increased. Nitrogen, water and electrolyte balance studies are in progress.

Electrolyte and water excretion in the hypophysectomized dog R C DE BODO, D P EARLE, JR, I L SCHWARTZ,* S J FARBER* AND E D PELLEGRINO * *Depts of Pharmacology, Medicine and Physiology, New York Univ College of Medicine, New York City*

The purpose of this investigation was to determine whether hypophysectomized dogs, while manifesting severe disturbances of carbohydrate and protein metabolism, reveal concurrent abnormalities in electrolyte and water excretion. The following observations were made on hypophysectomized dogs after maximal insulin hypersensitivity (more than 60-fold increase over normal) had developed (*Federation Proc* 7 116, 1948) and fasting produced hypoglycemic shock

1) The dogs responded to salt deprivation (sodium intake roughly 2 mEq daily for 3 weeks) in a normal fashion in that urinary excretion of sodium and chloride became negligible and there were only minor decreases in serum sodium. 2) The dogs' tolerance to acute administration of potassium appeared normal. During intravenous infusion of potassium at a rate of 0.5 mEq/min, potassium excretion increased promptly approaching or equalling the filtered load. 3) The excretion of water administered by stomach tube was very markedly delayed. When a water load of 40 ml/kg body weight was given only a small fraction was excreted in 3 hours (5-15%). 4) Glomerular filtration rate and renal plasma flow were reduced confirming earlier work of others. Glucose-T_m was also reduced. It is concluded that the hypophysectomized dog is able to conserve sodium and excrete potassium normally at a time when water excretion is impaired and the organic metabolism is gravely disturbed.

Absorption of phenol following application of 2% phenol in calamine and 'campho-phenique' to skin of experimental subjects WILLIAM B DEICHMANN, R RUEDEMANN* AND T MILLER * *Division of Pharmacology, Depts of Physiology and Pharmacology, and of Dermatology and Syphilology, Albany Med College, Albany, N Y*

One to 4 doses of 1 gm of phenol each were applied at 2-hour intervals to the skin (back, chest and legs) of 19 experimental subjects in the form of either 50 gm of 2% phenol in Calamine Lotion or 21 gm of Campho-Phenique liquid. This preparation contains 4.75% phenol and 10.86% camphor in aromatized mineral oil. Individuals donned clothing immediately after each application and did not remove them until termination of a 24- or 48-hour period of exposure. Blood phenol levels were followed for 3 days, using the method of Deichmann and Schafer (*Am J Clin Path* 12 129, 1942). 'Free' blood phenol rose from a control of about 0.15 to approximately 0.4 mg % after either one, two, three or four doses, each equivalent to 1 gm of phenol. This indicated that under the conditions employed the 'free' blood phenol level was not increased by repeated doses. 'Conjugated' blood phenol rose from about 0.35 to 1.0 mg % after application of one dose of 1 gm of phenol in either preparation. Each additional dose induced a higher peak of the 'conjugated' fraction. The highest mean concentration of 'conjugated' phenol of 1.92 mg % was obtained in the 4 subjects receiving 3 1-gm doses of phenol in Calamine. These results show that phenol is rapidly absorbed from the skin from these dilute preparations. The bulk is rapidly detoxified, as evidenced by a prompt rise in the 'conjugated' fraction. Application over a period

of 6 hours of 4 1-gm doses of phenol, as 2% phenol in Calamine or as Campho-Phenique Liquid, to the chest, back and legs did not raise the 'free' blood phenol more than a single application. It is quite possible that the clothing played a role in retarding the absorption of phenol. There were no signs of local irritation or systemic intoxication.

Distribution of muscle fibers in a single motor unit J S DENSLOW AND OLWEN R GUTENSOHN * *Kirksville College of Osteopathy and Surgery, Kirksville, Mo*

Experiments have been done in a study of the geographic arrangement of the group of muscle fibers in a single motor unit. Attempts to isolate single motor fibers to the peroneus longus (cat) have been made by sectioning all motor nerves to the lower extremity, except the nerve to the peroneus longus, and by splitting 7 L anterior root under a dissection microscope until given bundles contain one fiber to the peroneus longus. The identification of single fibers is made by a number of methods. When it appears that a given bundle contains but one fiber to the peroneus longus, pairs of recording electrodes are placed on the muscle and a 'map' of the location, pattern, etc. of the muscle action potential on the surface of the muscle is made. It has been observed a) that the action potential of a single motor unit may appear all over the surface of the muscle, although concentrated in certain areas, it may be found in a narrow strip in the long axis of the muscle or it may be limited to one corner of the muscle, b) the action potential may be mono-, di-, tri- or polyphasic, depending apparently on the orientation of the electrodes to active fibers and c) one pair of electrodes may pick up the action potential from one group of fibers in the unit while another pair, within 2-3 mm may pick up another. Experiments to determine the third dimension are now being done.

Physiological effect of plastic prosthesis for mitral valves in dogs G REHMI DENTON,* BENEDICT MASTRIANI,* CURTLAND BROWN, JR * AND HAROLD C WIGGERS *Dept of Physiology and Pharmacology, Albany Med College, Union Univ, Albany, N Y*

A prosthesis, made out of polyethylene, has been designed to replace mitral valves in dogs. Constructed without moving parts, designs have been produced to fit various study problems such as a) the effects of an essentially normal replacement for mitral valves, b) the situation with varying degrees of mitral stenosis and little regurgitation, c) the reverse, with no stenosis and marked regurgitation, or d) varying degrees of both stenosis and insufficiency. After 14 operations the technic for satisfactory insertion of these valve

substitutes was established. We now have several healthy dogs who show no ill effects 4-5 months after insertions of substitute mitral valves. Electrocardiograms were taken before, during and at repeated intervals following valve insertion to estimate the degree of cardiac damage entailed. Heart sounds and murmurs have been followed constantly and have been optically recorded. Fluoroscopic study of the heart and lungs has been carried out at frequent intervals. Recognizing that insertion of these valves is relatively safe and that certain degrees of stenosis and/or insufficiency can be tolerated, extensive cardiovascular and respiratory data are being collected on control dogs, prior to creating varying degrees and types of valvular incompetence by insertion of 'substitute mitral valves'. A stress test has been devised to measure the pulmóno-circulatory efficiency of dogs before and after insertion of substitute heart valves. The possible application of this procedure to the correction of valvular defects in the human is apparent.

Central summation following contralateral stimulation of tarsal chemoreceptors V G DETHIER (introduced by ARTHUR J DZIEMIAN) *Dept of Biology, Johns Hopkins Univ, Baltimore, Md*

When chemoreceptors on the leg of the blowfly are stimulated by certain sugars, the fly responds by extending its proboscis. Addition to sugar of a sufficient concentration of electrolyte or non-carbohydrate organic compound inhibits the response to sugar. When one leg is exposed to a threshold concentration of sucrose and the contralateral leg simultaneously to a subthreshold concentration of unacceptable compound (e.g. an alcohol), proboscis extension occurs. As the concentration of alcohol is increased, a point is reached where the response to sucrose is inhibited. This rejection threshold is identical with that obtained by exposing a single leg to mixtures of sucrose and alcohol. If one leg is exposed to a mixture of threshold sucrose plus one half threshold alcohol and the contralateral leg to varying concentrations of alcohol alone, a rejection is obtained when the sum of the alcohol concentrations stimulating each leg approximates that which is required to cause rejection when applied to a single leg. These results indicate 1) that the tarsi contain at least 2 types of chemoreceptors, one of which can be stimulated by sugar and initiates proboscis extension, the other of which can be stimulated by unacceptable compounds and prevents extension of the proboscis, or if the proboscis is already extended, causes its withdrawal, 2) that inhibition of response to sugar is a central phenomenon, 3) that within the CNS, possibly in the segmental ganglion, impulses from the

same type of receptors in the contralateral legs are summed

Acid phosphatases of chicken bone marrow H F DIERMEIER* AND V F LINDEMAN *Dept of Zoology, Syracuse Univ, Syracuse, N Y*

The results reported here on the acid phosphatases are the first of a comprehensive study of the enzyme systems of bone marrow. The method of Fisk and Subba Row (*J Biol Chem* 66 375, 1925) was used to determine inorganic phosphorus released after incubation of a water extract of marrow with the substrate for 15 minutes at 37°C. Results are expressed as μg (γ) of inorganic phosphorus released/100 mg of heat coagulable protein/min. Two acid phosphatases were found to be present. One, a phosphomonoesterase, with an optimum pH of 5.5 released 185.5 γ from disodium-monophenylphosphate. Mg or Mn ions had no effect on the activity in concentrations of 10^{-2} to 10^{-4} M but inhibited the activity approximately 50% when the concentration reached 10^{-2} M. Storage of the extract at 1°C for 5 hours did not decrease the activity of the extract. After 24 hours storage at 1°C 80% of the original activity remained. Dialysis for 18½ hours against distilled water reduced the activity 25%. Dialysis for 19 hours against 0.85% NaCl reduced the activity 35%. The activity is not restored by the addition of Mg ions. This enzyme did not actively attack adenylic acid, glucose-1-phosphate, glycerophosphate (52% α), or fructose diphosphate. A pyrophosphatase was also found to be present. It exhibits a broad pH optimum between pH 4.6 and 5.1. At optimum pH and optimum substrate concentration (0.004 to 0.005 M), inorganic phosphorus is released from sodium pyrophosphate at a rate of 292.66 γ , and from adenosinetriphosphate at a rate of 261.33 γ .

Refractory period and excitability of isolated auricle and papillary muscle of the cat J R DI PALMA AND A V MASCATELLO* *Dept of Medicine, Long Island College of Medicine, Brooklyn, N Y*

A specially designed square wave dual pulse stimulator was used. The muscles were suspended in oxygenated Locke's Solution at a pH of 7.3. Electrodes were of Ag coated with AgCl. Strength-duration curves were determined on 22 auricles and 19 papillary muscles at a temperature of 37.5°C. For the auricle the mean rheobase was 0.8 ma (S.D. \pm 0.14) and the mean chronaxie was 4.7 ms (S.D. \pm 1.7). The papillary muscle had a mean rheobase of 0.3 ma (S.D. \pm 0.25) and a mean chronaxie of 3.5 ms (S.D. \pm 2.0). Thus the papillary muscle was rather more excitable than the auricle. This was confirmed in other experiments. The absolute refractory period was determined over a range of rates of from 35 to 250

per min and at temperatures from 24° to 39°C. Both auricle and papillary muscle showed a shortening of the refractory period as the rate of stimulation increased. This decrease in refractory period followed an exponential curve. A decrease in temperature of the bath increased the refractory period. Between the temperatures of 27° and 36°C this relationship was a linear one. In all comparable instances the refractory period of the auricle was shorter than that of the papillary muscle. An interesting finding was that under certain conditions the auricle and papillary muscle showed summation to two successive stimuli. In the case of papillary muscle at a temperature of below 27°C even incomplete tetanus could be demonstrated. No relationship between refractory period and excitability was found.

A study of alkali hematin prepared from hemin HAROLD L DOBSON,* JOSEPH H GAST* AND JAMES A GREENE *Depts of Biochemistry and Medicine, Baylor Univ College of Medicine, Houston, Texas*

In an effort to obtain a simple reproducible alkali hematin standard, 18 samples of hemin were compared. These samples were prepared by the method of Fischer, from human blood, to study the effect of variations in temperature, amount of blood added, and stirring on the yield and purity. After carefully washing and drying, but before recrystallization, these samples were compared analytically and spectrophotometrically. The color intensity of the solution of hemin in 0.1 N sodium hydroxide, measured on a Klett-Sumner-son photoelectric colorimeter with filter no. 54 (maximum transmission 525-530 m μ), was fully developed within 5 minutes at room temperature and was stable over a period of at least 3 months. The optical density was reproducible. The calculated hemin content of an alkalinized sample of whole blood of known hemoglobin concentration was arbitrarily accepted as the alkaline hematin standard. In comparison studies on the purity of the samples there was a 12.1% difference between the iron and alkaline hematin analyses, with the iron giving the higher values. This difference may be eliminated by adding a small amount of human plasma to the alkaline hematin determination. Spectrophotometric studies indicate that there is a change in absorption over the first nine hours after the hemin was put into solution, after this period of time the spectrum remained stable. Other absorption spectrum studies indicate that alkaline hematin, prepared from hemin, changes with the addition of fresh human plasma.

Adrenal cortex and water metabolism in the golden hamster ROBERT L DORSEY AND W R BOSS (introduced by ROBERT GAUNT) *Dept of Zoology, Syracuse Univ, Syracuse, N Y*

Two hundred-thirty fasted adult normal or adrenalectomized male hamsters were administered 5% of body weight of normal saline or distilled water by stomach tube. Normal animals receiving a single dose of distilled water or saline required an average of $2\frac{1}{2}$ and 4 hours respectively to excrete 50% of the fluid administered. Four hourly doses of water or saline retarded the 50% excretion time to 7 hours for water and 5 hours for the saline. Three half-hourly doses of water produced water intoxication and four doses killed 75% of the animals. Small doses (0.25 mg) of DCA protected against water intoxication and did so more effectively than 2.25 mg of ICA. When animals adrenalectomized 18 hours were hydrated with a single dose of water it required 11 hours for the 50% excretion time. Saline drinking solution was refused by adrenalectomized hamsters, but maintained life and the diuretic response to water when given by stomach tube. DCA (0.25 mg/day) maintained both body weight and water diuresis. Water diuresis tests exceeded normal in animals maintained on very small doses of DCA (0.025 mg/day) plus saline. The hamster differs markedly from rats and mice in its relative inability to excrete water rapidly, in its susceptibility to and symptoms of water intoxication, in the greater diuretic activity of DCA and saline both in normal and adrenalectomized animals, and in its naturally low water exchange.

Pulmonary 'capillary' pressure as an index of left atrial mean pressure in dogs JAMES W. DOW AND RICHARD GORLIN (introduced by GEORGE W. THORN) *Dept. of Pediatrics, Children's Medical Center, the Medical Clinic, Peter Bent Brigham Hospital, and the Depts. of Pediatrics and Medicine, Harvard Med. School, Boston, Mass.*

In 18 dogs, weighing 8-18 kg, each previously anesthetized with Nembutal, no. 7 or no. 8 Courmand catheters were inserted under fluoroscopic control 1) via a jugular vein into the pulmonary artery and advanced to occlude a terminal branch in order to measure pulmonary 'capillary' pressure, 2) via a femoral artery through the left ventricle into the left atrium. Phasic and mean pressures were recorded in these areas by Sanborn electromanometers. Alterations in pulmonary blood volume and flow and changes in respiratory excursion were effected by 1) rapid intravenous infusion of 10% dextrose in saline, 2) severe graded anoxia (0-6%), 3) experimental atrial septal defect, 4) respiratory outflow obstruction and mild positive pressure breathing. The average difference in mean pressures in the pulmonary 'capillaries' and left atrium was negligible under the above conditions, although the range varied from 0 to 4 mm Hg in 49 observations. These experi-

ments demonstrate that pulmonary 'capillary' mean pressure reliably equals left atrial mean pressure at rest and during major circulatory and respiratory variations. It is believed that either the gradient from pulmonary capillary to left atrium approximates the error of measurement of true pulmonary capillary pressure, or the pressure gradient is so small as to be undetectable by the recording methods utilized in this study.

Prototypal curves of dye concentration for cardiac output by injection method PHILIP DOW AND W. F. HAMILTON *Dept. of Physiology, Univ. of Georgia School of Medicine, Augusta*

The validity of the determination of cardiac output by a single rapid injection of an intravascular dye depends upon graphical recognition of recirculation of the dye. This is often difficult when flow is sluggish and intrathoracic blood volume is large. Previously published attempts to circumvent this limitation by 'theoretical' treatments have neglected one or another of the essential determinants. The varying velocity of parts of a single stream, the different lengths of path traversed, the relationship between volume and flow and the discontinuous filling and partial emptying of both sides of the heart must all be accounted for. Therefore an empirical treatment has seemed a more promising approach to the problem of discovering uniform characteristics which would permit use of the earlier, presumably less distorted, portions of the curves. Current studies of several extensive series of experiments taken from departmental files have yielded evidence of significant uniformities among curves from extremely different cardiovascular conditions. The relationship between peak time and appearance time exhibits a strong central tendency (average ratio 1.5) and its variation appears to be random rather than systematic. Employment of a logarithmic time scale improves the symmetry of rise and fall, but the scatter is much less satisfactory. Further manipulations, and comparisons with direct Fick results are in progress.

Effect of ACh on simultaneously recorded ECG and cardiogram of the heart of *Venus mercenaria* FENWORTH DOWNING,* A. L. DUNN* AND A. R. MCINTYRE *Dept. of Physiology and Pharmacology, Univ. of Nebraska College of Medicine, Omaha*

Simultaneous kymographic recordings by both a direct writing ECG and mechanograph and by a C-R tube were made possible by the use of a Transducer (RCA 5734) arranged in such a manner that each systole deflected both the RCA 5734 plate-shaft and a direct writing mechanograph. A silver-silver-chloride tip on an enamelled No. 40 copper wire served as one electrode and also connected one end of the isolated heart to the

Transducer and thence to the writing lever. The characteristic ECG consists of a positive deflection of approximately 100 microvolts of 0.1-0.5 seconds duration followed by negative deflection of 500-900 microvolts. Wide variations in these figures were found in 'normal' hearts. The activity normally arises in the atrium but reversal of ECG phase and direction of contraction is seen following drugs especially Ergotrate which may cause arrest in systole with electrical 'silence'. The isotonic contractions expressed as work may exceed 15,000 gm/cm/24 hr. ACh reduces the ECG-emf more than the mechanograph amplitude. Observations of the ECG renders possible the detection of 0.000025 gamma ACh/ml. Very low concentrations of ACh may slow the heart rate without changing the systolic amplitude and without affecting the ECG. Full technical details and experimental data will be published.

Peptidase activity of paraffin-embedded tissue

W. L. DOYLE, *Dept of Anatomy, Univ of Chicago, Chicago, Ill*

The preparation of accurately thin, serial microtome sections of frozen tissues for quantitative histochemical studies on enzymes requires special and inconvenient procedures. Except for certain notably resistant esterases, the manipulative advantages of paraffin embedding have been discarded out of regard for the lability of most enzymes. The denaturing action of fixatives prior to embedding can be avoided by quick-freezing followed by dehydration *in vacuo* in the frozen state (Altmann-Gersh technique). The stability of a relatively labile peptidase to subsequent heating is shown as follows. Frozen-dried rabbit appendix was infiltrated with paraffin at 65°C *in vacuo* for 40 minutes. The paraffin was subsequently extracted with benzene at 45°C for twenty minutes. These times and temperatures exceed normal requirements. With respect to the hydrolysis of alanyl-glycine the treated tissue not only showed no loss of activity but also gave better aqueous extracts due to removal of fat. The method has promise for other enzymes usually considered too labile to permit embedding in paraffin.

Slope of the CO₂ curve obtained by breathing into the rapid infra-red gas analyzer. A. B. DuBois,* A. Soffer,* R. C. Fowler* and W. O. Fenn. *Dept of Physiology and Vital Economics, Univ of Rochester School of Medicine and Dentistry, Rochester, N. Y.*

The gas analyzer of R. C. Fowler gives a photographic record of the CO₂ concentration as a function of time during a single expiration. This curve of expiration in 17 normal subjects shows a rapid S-shaped rise lasting 1 to 1.5 seconds abruptly changing to a plateau that gradually

risks with time. The plateau ascends more steeply with work and hyperventilation. No plateau was reached in subjects with severe emphysema. In one emphysematous subject, normal expiration gave 6% CO₂, full expiration 10% CO₂. However, in normal subjects end readings of deep and shallow expirations delivered in the same time showed differences in percent CO₂ which are small compared to changes in the plateau with time. Thus, the ventilation to bloodflow ratio was not much altered at different lung volumes, although small differences defy observation. The average slope of the CO₂ plateau in resting normal subjects is 0.11% CO₂/sec (± 0.03). This is less than expected for overall CO₂ output. Diffusion of CO₂ from blood to alveolar air is greater during normal inspiration than expiration, being several times greater for a single deep breath. This cannot be explained without postulating inordinately large changes in blood flow or a blood and tissue reservoir of CO₂ at alveolar concentration as a source of the extra CO₂ appearing during inspiration. Such a reservoir also diminishes the expiratory CO₂ slope by acting as the mathematical equivalent of an additional or 'phantom' residual air.

Influence of pantothenic acid on response of adrenalectomized and intact rats to stress

MARY E. DUMM* and ELAINE P. RALLI. *Labs of the Dept of Medicine, New York Univ College of Medicine, New York City*

The response of adrenalectomized and intact rats to stress has been evaluated by 1) determining the capacity of the rats to swim in water at 18°C, 2) following the total number of white blood cells and lymphocytes for 6 hours after swimming for 25 minutes at 25°C and for 8 hours after the injection of ACTH, and 3) determining the blood sugar of rats (fasting and non-fasting) after swimming 25 minutes at 25°C. Intact rats receiving experimental diets varying only in their pantothenate content, swam 62 ± 12 minutes on 4 mg of pantothenate daily, 29 ± 4 minutes on 0.1 mg of pantothenate, 24 ± 4 minutes on 4 mg of pantothenyl alcohol, and 17 ± 2 minutes on the dog chow diet which supplies about 0.1 mg of pantothenate daily. Adrenalectomized rats swam 38 ± 6 minutes on 4 mg of pantothenate daily and 19 ± 2 minutes on 0.1 mg of pantothenate. Both in the adrenalectomized and intact rats the leucocyte and lymphocyte responses to swimming and to ACTH were modified by the presence or absence of pantothenate in the diet. Following swimming, the average blood sugars of non-fasted, adrenalectomized rats, receiving the 4 mg pantothenate diet, fell from 119 ± 4 to 90 ± 4 mg %, compared with a decrease from 107 ± 6 to 69 ± 4 mg % by the adrenalectomized rats on 0.1 mg of

pantothenate daily, and a decrease from 101 ± 5 to 71 ± 9 mg % by the pantothenate deficient adrenalectomized rats. In the fasted adrenalectomized rats on the 4 mg pantothenate diet the average blood sugar fell from 65 ± 5 to 53 ± 4 mg % compared with a decrease from 71 ± 3 to 43 ± 3 mg % by the rats on the 0.1 mg pantothenate diet, and a decrease from 59 to 46 mg % by the pantothenate deficient rats. These results suggest that calcium pantothenate influences the ability of both intact and adrenalectomized rats to withstand stress.

Factors involved in evaluation of pulmonary edema at autopsy STANLEY H. DURLACHER, WILLIAM G. BANFIELD* AND A. DOROTHY BERGNER*
Pathology Section, Medical Div., Army Chemical Center, Md.

The ratio of lung to body weight has been determined in rabbits immediately and at intervals after sacrifice by a variety of procedures. Methods of sacrifice have included exsanguination, air embolism, electrocution, ether, rabbit punch, pentobarbital sodium by various routes and intracardiac saturated magnesium sulfate solutions. Histological examination of the lungs was made in all instances. The ratio of lung weight to body weight increased after death by all methods except exsanguination. The greatest increase occurred in animals sacrificed with pentobarbital sodium or magnesium sulfate solutions when introduced into the blood stream rapidly and in such fashion that high concentrations were present in the pulmonary vasculature after death. Under these conditions the lung weight to body weight ratio was 2 to 3 times greater after a 3-hour interval than was the ratio found in animals killed by the same materials administered by other routes. Increase in lung weight was due largely to accumulation of proteinaceous fluid within the alveoli, although a small portion of the increased weight was due to clotted blood remaining in the pulmonary blood vessels. When quantitative estimations of the degree of pulmonary edema present at autopsy are desired, rapid exsanguination is the most satisfactory method of sacrifice. In instances where this procedure is not feasible, air embolism should be used.

Metabolic response of epileptic patients to adrenaline A. DURY, J. W. HOLLER* AND C. SMITH*
Dorn Lab. Med. Research, Bradford Hospital, Bradford, Pa. and Depts. of Medicine and Surgery, Univ. of Rochester School of Medicine, Rochester, N. Y.

The effect of a single i.m. injection of 0.4 ml. aq. adrenaline (1:1000) upon the plasma potassium, glucose, absolute number of eosinophiles, and other blood constituents was measured in epileptic and Addisonian patients, and normal adults.

The percentage change in these constituents from the overnight-fast level was calculated for the periods of 4, 20, 60, and 120 minutes after an injection of adrenaline. The mean change of the blood glucose in normal adults was +44% and +47% after 20 and 60 minutes, respectively, and at pre-injection level after 120 minutes. The mean change of the blood glucose in Addisonians was +27% and +22% and in the epileptics was +27% and +25% after 20 and 60 minutes, respectively. The mean change in the plasma potassium in normal adults rose slightly after 4 minutes, was lowest after 20 minutes and at pre-injection level and slightly above after 60 and 120 minutes. In the epileptics and Addisonians the mean plasma potassium levels were below preinjection means 4, 20, and 60 minutes after adrenaline injection. Maximum change in the Addisonians was -20%, and in the epileptics -8%. The mean change in circulating eosinophiles after adrenaline injection decreased at a much slower rate and to a lesser extent in the epileptic group than the normal adults. Placebo injection of physiological saline in epileptics did not induce any change in these blood constituents. These data suggest that the mobilization of glucose into the blood and the metabolism of potassium in epileptic patients are comparable to Addisonians.

Physiologic responses of certain animals and isolated preparations to mixtures of snake venoms and egg yolk MURRAY DWORETZKY AND P. BOQUET (introduced by F. C. MANN)
Inst. of Experimental Medicine, Mayo Foundation, Rochester, Minn. and Pasteur Inst., Paris, France

Each of 8 different snake venoms when incubated with 40% egg yolk produced a substance extremely toxic for rabbits, cats and guinea pigs, but less toxic for dogs. Injections of equal amounts of the egg yolk emulsion alone were without toxic effect. The snake venoms were added to the mixture in nontoxic doses or they were neutralized by antivenom or inactivated by boiling the mixture after incubation. For convenience this material has been called the D-L substance since it was first described by Delezenne and Ledebt. Its effects on the animals mentioned strikingly resemble those caused by large doses of histamine or by anaphylactic shock. However, the D-L substance is not counteracted by benadryl or epinephrine. Furthermore, it causes immediate marked relaxation of the isolated guinea pig ileum when it has been contracted by histamine, acetylcholine or cobra venom. These findings have led to the conclusion that the D-L substance is not histamine. Mixtures of certain snake venoms incubated with other materials such as lymph, homogenized milk, homogenized rabbit muscle

or brain did not produce a toxic substance. The effects on the blood pressure and respiration of the rabbit and cat were indistinguishable from those following clamping of the common pulmonary artery. It has been demonstrated by vinyl acetate casts made of the pulmonary vascular system of cats and rabbits that death following the injection of the D-L substances resulted from occlusive spasm of the secondary pulmonary arteries.

Coronary vasodilation following intracoronary injections R. W. ECKSTEIN, J. CHAMBLISS,* J. DEMMING* AND K. WELLS * *Dept of Medicine, Western Reserve Univ., Cleveland, Ohio*

Total left coronary flow was measured in anesthetized heparinized open-chest dogs under artificial respiration. Blood was led from a carotid artery into a constant pressure chamber through a Shipley recording rotameter and thence into the common left coronary artery which was cannulated through the left subclavian artery. Injections were made through the rubber tube between the rotameter and the coronary cannula. It was accidentally found that rapid injections of blood, saline, or plasma in amounts of 0.1-0.2 cc through small needles results in large increases in blood flow, lasting from 5-30 seconds not attributable to pressure or viscosity changes. Likewise, when blood in a syringe is rapidly injected into large amounts of blood in a beaker, the blood in the beaker develops a potent vasodilator. The activity of this material steadily decreases upon standing during a 30-45 minute period, after which time activity is absent. There is evidence that this vasodilator is a product of the mechanical destruction of red cells. Its effect is not abolished by atropine and its behavior is not that of histamine. Spectrographic analysis shows that it is probably ADP or ATP and is identical with 'Früh gift'.

Adrenal cortex and survival of rats after x-irradiation ABRAHAM EDELMANN *Brookhaven Natl Lab., Upton, N. Y.*

Protecting the adrenals of male rats by means of lead shields placed about the glands significantly increased the survival incidence following 850 r of x-irradiation (160 KVP, 10 ma, 0.15 mm Cu). The x-irradiation (650 r) shortens the lives of adrenalectomized rats from an average of 8 days to 4 days. Substitution therapy in the adrenalectomized rat is effective inasmuch as 3 cc/day of a whole gland adrenal extract (Upjohn) or 5 mg/day of desoxycorticosterone acetate resulted in 20 and 40% mortalities respectively at 15 days after 600 r, whereas 90% of the adrenalectomized controls were dead at this time. It is thought that the adrenal cortical response to x-irradiation is similar to that following any other stress.

Blood flow distribution in the heated dog N. E. EDERSTROM *Dept of Physiology, St. Louis Univ School of Medicine, St. Louis, Mo.*

Dogs anesthetized with pentobarbital were warmed gradually by lamps until a lethal temperature was reached. Blood flows were recorded from the foot pads and tongue by means of the photoelectric plethysmograph. With an increase in rectal temperature blood flows in the foot pads decreased until they reached about one-half the normal as the lethal point of 45°C was approached. In contrast, blood flows in the tongue increased with the rise in body temperature, reaching about double the normal level at 43°C, and then declined abruptly between 43 and 44°. The foot pad surfaces, although shielded from direct heating, increased in temperature despite the drop in blood flows. Calculation of the thermal equilibria indicate an increased convection by the blood stream due to a greater A-V temperature difference. The tongue surface increased in temperature as flow increased, reaching a peak simultaneously with blood flows at 43°. Surface temperatures in both areas fell as blood flow declined at the approach of lethal body temperatures. Blood pressure, heart rate, respiratory rate increased with the rise in body temperature, but declined near the lethal level. These observations indicate that in hyperthermia the blood of the dog is shunted to the heat dissipating area provided by the tongue, and away from the skin surface and consequent exposure to the hot environment. This redistribution of the blood in the non-sweating dog is therefore opposite in direction to that occurring in a sweating man.

Urine amine levels in normotensive and hypertensive subjects EDWARD F. EDINGER, JR.* AND NORMAN S. OLSEN *Hypertension Division, Dept of Internal Medicine, and the Oscar Johnson Inst., Washington Univ School of Medicine, St. Louis, Mo.*

The presence of pressor substances in urine has been described previously by several workers. These substances have been thought to be amines. For this reason the amine content of urine from normotensive and hypertensive subjects has been studied. Using a modification of Richter's pierate method for amines, freshly voided morning specimens of urine were analyzed. Creatinine concentrations were also measured and urine amine-creatinine ratios calculated. It was found that the urine specimens from normal individuals contained significant quantities of free amine, measured in terms of isoamylamine. The urine amine-creatinine ratios of normal non-smokers fell within a narrow range, whereas smokers tended to have higher ratios. Certain hypertensive patients had low urine amine levels with reduced

amine creatinine ratios as compared with the normal controls

Oximetric determinations of cardiac output in man at rest and mild exertion JAMES O. ELAM*, WILLIAM SLEATOR*, W. N. ELAM* AND H. L. WHITE *Lab. of Thoracic Physiology and Dept. of Physiology, Washington Univ. School of Medicine, St. Louis, Mo.*

Changes in arterio-venous oxygen difference with the increased cardiac output of mild exertion in normal subjects were studied by means of the modified oximetric method of Matthes previously described (*Federation Proc.* 7: 104). Arterial and mixed venous oxygen saturations were recorded while the subject breathed air and rebreathed the helium-alveolar air mixture. The red and infrared light transmissions of the histamine-flushed pinna were recorded separately, with occlusion to 220–280 mm Hg to obtain bloodless values. Oxygen saturations were deduced from the transmission data by means of a calibration curve previously established by means of Van Slyke analyses. Greatest deviation of oximetric value from Van Slyke value was $\pm 4\%$. Hemoglobin determinations were used to obtain oxygen contents from saturation values. Arterio-venous oxygen difference and oxygen consumption were determined after the subject had been sitting at rest for 30 minutes and at 5-minute intervals 10 minutes after exertion was started. Repeated cardiac output determinations while each subject was in a given steady state showed mean deviations from their means which averaged 4–2% for 48 measurements on 4 subjects. Increase of oxygen consumption up to 20% above the resting value was sometimes accompanied by a decrease in arterio-venous oxygen difference. When oxygen consumption was increased more than 20% above the resting value the arterio-venous oxygen difference usually increased. Except in one experiment, the percentage increase in arterio-venous difference was less than that in cardiac output.

Some responses of the ear to high frequency sound DONALD H. ELDRIDGE, JR. (introduced by E. A. PINSON) *Aero Med. Lab., Air Materiel Command, Wright-Patterson Air Force Base, Dayton, Ohio.*

Davis *et al.* (*OSRD Final Report on Temporary Deafness Following Exposure to Loud Tones and Noise*, September 1943) showed that exposure to pure tones (speech frequency range) produced temporary deafness principally in the octave above the exposure tone. This observation is shown to hold for audible tones at frequencies above 6000 cps, provided the sound level is not high enough to overload the ear. Subjects exposed

to tones from a siren (6–40 Kcps) at 150–158 db ref. 0.0002 dynes/cm² reported hearing unusual sounds not present in the sound field and subsequently showed elevations of the threshold for pure tones at frequencies considerably below the exposure tone. Moderate background noise combined with varying amounts of frequency and intensity modulation made necessary experiments designed to separate the factors producing this elevation threshold. A possible mechanism for the production of the low frequency hearing loss was indicated when subjects were exposed to a very pure tone of 9200 cps and 140–146 db produced by an aluminum rod in longitudinal vibration. The subject heard one or more of the subharmonics of the tone well enough to match them to a pure tone presented to the opposite ear. The first subharmonic radiated from the subject's ear and was heard by other observers. The measured level of the radiated subharmonic was 60–80 db below the exposure tone.

Alterations in renal hemodynamics and excretion of electrolytes J. R. ELKINTON, A. P. CROSLLEY, JR., *H. G. BARKER,* AND J. K. CLARK **Harrison Dept. of Research Surgery, School of Medicine Hospital, Univ. of Pennsylvania, Philadelphia.*

Following control periods renal dynamics were altered in normal human subjects by 3 procedures: 1) infusion of concentrated salt-poor albumin, 2) injection of Neosynephrine, and 3) tilting 60° from the horizontal position. The glomerular filtration rate (GFR) was obtained from clearances of mannitol, inulin, or endogenous creatinine. The renal plasma flow (RPF) was measured with paraaminohippurate as effective flow by clearances in the Neosynephrine experiments and in the others as total flow by the direct Fick method with a catheter in the renal vein. Following concentrated albumin when the RPF rose markedly but the GFR was unchanged, the excretion rates of Na and K increased while that of Cl was essentially unaltered. Following Neosynephrine when the RPF fell moderately without change in the GFR, the excretion rates of Na, K and Cl fell, and that of Na returned to the control level when the RPF did likewise. On tilting when both the RPF and the GFR fell, the excretion rate of Na decreased markedly, and failed to return to control levels when the RPF and the GFR were restored, excretion of K and Cl decreased in equivocal amounts. These data indicate that, under the conditions of these experiments and within the limitations of the methods, sodium excretion appears to be determined by changes in tubular transfers rather than by changes in glomerular filtration, and is most closely correlated with changes in renal blood flow and filtration fraction. The dissociation seen during recovery periods in the tilt experi-

ments supports the fact that the correlation does not necessarily result from a simple causal relationship

Increased fragility of erythrocytes during experimental hypertension M M ELLIS, M D ELLIS* AND G C RAU * *Dept of Physiology and Pharmacology, Univ of Missouri Med School, Columbia*

Chronic hypertension was induced in adult dogs by encapsulating first the right kidney and some 14 days later the left kidney with plastic as described by Rau (in press) A 5-cc blood sample was drawn from the jugular vein of each dog every 7-10 days throughout the 60-day period of the test, about 30 minutes after the i p injection of 32.5 mg/kg of sodium pentobarbital (Nembutal) The blood was diluted immediately 1:100 with 0.71% NaCl solution buffered to pH 7.4 with disodium phosphate The blood mixture was incubated in pyrex test tubes for 22 hours in an electrically operated water bath at 37°C Haemolysis was read with a spectrophotometer The blood pressure rose from normals around 120 mm Hg to 150-180 after encapsulation of right kidney, held or fell slightly until the left kidney was encapsulated, and then rose to 198 or better The amount of haemolysis at the end of 22 hours incubation increased with a slight lag, as the blood pressure rose When the blood pressure held or fell before the encapsulation of the second kidney the 22-hour haemolysis decreased but did not return to the normal level Following encapsulation of both kidneys the 22-hour haemolysis again increased as the blood pressure rose, remaining well above normal to the end of the experiment some 30 days after the last operation These increases in 22 hour haemolysis varied from 100 to 270% in terms of the normal values Comparable results were obtained using other strengths of saline

Dose response data in man following orally administered or injected lipo-adrenal cortical extract FRED ELMADJIAN (introduced by HUDSON HOAGLAND) *Worcester Foundation for Experimental Biology, Shrewsbury, Mass*

Lipo-adrenal cortical extract (Upjohn) was given to human subjects in doses of 20 cc, 10 cc, 5.0 cc, and 2.5 cc intramuscularly and orally Changes from premedication levels were noted in the rate of urine excretion, creatinine, 17-ketosteroids, uric acid, potassium and sodium excretion as well as changes of blood lymphocytes and eosinophils at intervals during a period of 5 hours after the administration of the extract Considering the overall adrenal cortical responses noted in these dosage ranges the effectiveness of the orally administered extract proved to be comparable to that of the injected extract Of the adrenal cortical indices determined urine volume and eosinophil counts were more proportional to the dosage than

the sodium, potassium and 17-ketosteroid excretions Uric acid excretion showed the least relative response to the quantitatively increasing dosage The directions of the changes obtained in the adrenal response measures for orally administered extract were the same as those produced by intramuscular injection of the extract with all of the indices except that of sodium In all dosage ranges employed the intramuscularly administered extract clearly showed a decrease in the sodium excretion especially in the period from the 2nd to the 5th hour after the injection, while the orally administered hormone indicated an increase in the sodium excretion in the same period

Action of valves of the beating mammalian heart with simultaneous records of ECG, vibrations and sounds (motion picture) HIRAM E ESSEX, H L SMITH* AND E J BALDES *Mayo Clinic and Mayo Foundation, Rochester, Minn*

The behavior of the pulmonic, aortic, mitral and tricuspid valves of isolated beating mammalian hearts will be shown Attention will be given to the sphincteric action of the auriculo-ventricular ring which constricts in systole and dilates in diastole It will likewise be shown that the mitral valves are inactive when fluid is drawn from the ventricular cavities and that auricular pressure is not necessary for opening the valves since they open freely when the auricular walls have been incised and retracted The mitral and tricuspid valves will be excised and the effect on the cardiac sounds will be demonstrated

Spreading cortical depression CARL F ESSIG* AND WADE H MARSHALL *Intramural Research Branch, National Inst of Mental Health and Lab of Physical Biology, Exper Biology and Medicine Inst, National Inst of Health, Bethesda, Md*

A cat or monkey preparation of exposed cortex maintained under physiological conditions rarely produces spreading depressions We have developed 3 almost certain methods of producing the reaction 1) radical internal dehydration, 2) cooling the surface of the cortex approximately 10°C, and 3) exposure to room air for several hours A 4th but uncertain method is some unknown traumatic factor in surgical procedure An occasional monkey preparation will yield the reaction within the 1st hour after exposure to room air Failures of reactions are correlated with highly negative cortical base line voltages The chilled cortex (monkey) shows 4 definite components D1, D2, D3, and D4 D1 jumps the central sulcus, D2 follows the cortex or pia membrane D1 and D2 velocities are approximately 0.03 mm/sec D3 velocity is about 0.0053 mm/sec, and D4 velocity is about 0.0035 mm/sec The D1, D2, and D3 reactions are obtained after prolonged exposure to room air but at 1.5-3 times the above velocities

In both cooled and room air exposed preparation D4 is not always seen. The reactions develop gradually to the same pattern that can be obtained in 10 minutes by cooling the cortex. The initial stages of development of the phenomena can be seen within 15 minutes after exposure to room air.

Plasma and erythrocytic ion concentrations in infant diarrhea J N ETTELDORF* AND R R OVERMAN *Divisions of Pediatrics and Physiology, Univ of Tennessee College of Medicine, Memphis*

Determinations of plasma Na, K, Cl, Ca, CO₂ content, protein, erythrocyte Na, K, Cl, blood pH, NPN, and hematocrit were made on the following groups of infants: 81 normal, 26 with diarrhea before treatment, 40 with diarrhea receiving parenteral NaCl, sodium lactate, blood and/or plasma, and glucose, 95 with diarrhea receiving the above treatment plus KCl (Solutions administered contained 5.6 to 16.0 mEq/l of K). In normal infants average values were similar to those of normal adults except the erythrocyte Na was higher (19.4 compared to 15.3 mEq/l), hematocrit lower (35.6%), and plasma protein lower (6.3 compared to 7.6 gm%). The following observations were made on patients before treatment: a) Plasma: reduced K (4.6–3.8 mEq/l), Na (141–133 mEq/l), CO₂ (54–37 vols %), pH (7.40–7.36), normal Cl; b) Erythrocytes: reduced K (102–95 mEq/l), Cl (64–60 mEq/l), elevated Na (19.4–20.2 mEq/l); c) Blood: NPN elevated (30–44 mg%). In treated infants receiving no K, plasma Na was higher (136 mEq/l) but K lower (3.3 mEq/l) than the untreated group, erythrocyte Na was definitely elevated (23.2 mEq/l) but K and Cl unchanged. CO₂ content and pH were normal but NPN remained high (39 mg%). The average plasma K of all infants receiving K was not significantly higher than that of the preceding group, erythrocyte Na was less elevated (21.4 mEq/l). Otherwise the 2 groups of treated infants were similar. A series of diarrheal patients are being investigated to whom larger doses of KCl are being administered.

Studies on the physical properties of bone F GAYNOR EVANS AND MILTON LEBOW (introduced by ERNEST GARDNER) *Dept of Anatomy and Engineering Mechanics, Wayne Univ, Detroit, Mich*

The tensile strength and modulus of elasticity were determined for 103 samples of human bone from 9 femora of 3 Negro females and 5 white males. All but 2 bones were from dissecting room cadavers. In contrast to most earlier studies of this nature, the samples were tested under direct tension. The tests were made in a Baldwin-Southwark Universal testing-machine calibrated to an accuracy of 2%. The deformations were measured by a Porter-Lipp extensometer over a one inch

gauge length. Samples were obtained from the compacta of the antero-lateral, antero-medial, postero-lateral and postero-medial quadrants of the proximal, middle and distal thirds of the shaft. An attempt was made to standardize the size of the samples. A fairly complete series of samples was obtained from the femur of a 26-year-old and a 45-year-old Negro female and a 64-year-old white male. In these 3 bones the samples from the lateral half of the shaft had a higher average tensile strength than those from the medial half. This difference was most consistent and conspicuous in the proximal third of the shaft. Where the sample series was complete the average tensile strength of all quadrants of the middle third of the shaft was the greatest. No consistent relationship between tensile strength and age of the individual was noted. Similar studies on other bones will be reported.

Pyruvate metabolism in rabbit bone marrow

JOHN D EVANS (introduced by DAYTON J EDWARDS) *Dept of Physiology, Cornell Univ Med College, New York City*

Previous *in vitro* studies have shown that marrow cells suspended in Ringer-bicarbonate at pH 7.3 exhibit a respiratory quotient of 0.84 in the absence of glucose. If glucose is added to the medium the R.Q. of marrow is raised to 0.95. In the present study it is observed that when pyruvate is added to marrow, active utilization occurs and the R.Q. is elevated to 1.11. At a concentration of 1 mg of pyruvate/ml of marrow suspension 40% of the pyruvate disappears in 4 hours, but despite this rapid disappearance the rate of oxygen consumption is not increased. In 36 experiments the average rate of pyruvate utilization is 5.7 μ g/mg of cell protein/hr. There is an average production rate of 3.1 μ g of lactic acid/mg/hr and an average evolution of 3.2 μ l of respiratory CO₂/mg/hr. These figures represent a pyruvate:lactate:carbon dioxide ratio approximating 2:1:4. It is concluded from the aerobic experiments that marrow preferentially metabolizes added glucose and pyruvate, thereby producing high respiratory quotients which approximate the theoretical values for those substances. Anaerobically, pyruvate is converted to lactate in approximately a 1:1 ratio. The amount of pyruvate utilized in the absence of oxygen averages 4.2 μ g/mg/hr.

Fibrinolysokinase activity in tissues JOHN H FERGUSON AND JESSICA H LEWIS *Dept of Physiology, Univ of North Carolina, Chapel Hill*

Tissue substances capable of activating pro-fibrinolysin to active fibrinolysin have been described by Astrup and Permin, Permin, and Taghon. Various dog tissues were fractionated into 7 fractions, of different particle size, by differential centrifugation and each of these frac-

tions was tested for fibrinolysokinase activity on dog serum profibrinolysin. The 37 different tissues studied were divided into three groups: *Group I*, those tissues having one or more fractions which showed appreciable kinase activity, *Group II*, those tissues having one or more fractions which showed minimal kinase activity, and *Group III*, those tissues from which no fractions showed kinase activity. Kinase activity was usually concentrated in Fractions IV (Claude's large granules) and VI (Claude's microsomes). Fraction VII, the saline soluble portion, never showed kinase activity and, in fact, usually contained some antifibrinolysin. Tissues included in *Group I* were lung, uterus (pregnant and non-pregnant), pancreas, gall bladder, lymph gland, vein and urine. Fractions IV and VI of lung were chosen for special study. Kinase activity could not be extracted with common organic solvents. The kinase was unstable, disappearing rapidly at 37°C or higher, slowly at room temperature, and very slowly at 0°C. Freezing and storage at -20° resulted in a marked initial loss of activity, with little change thereafter. The activation of profibrinolysin with the lung fractions was found to be slow in comparison to that produced by staphylokinase but apparently the same enzyme precursor was activated in each case. Whole serum and plasma treated with these fractions showed little fibrinolytic activity in comparison with partially purified profibrinolysin.

Comparison of the A-A gradient determined by different methods BENJAMIN G. FERRIS, JR. (introduced by WILLIAM H. FORBES) *Dept of Physiology, Harvard School of Public Health, Boston, Mass.*

Alveolar-arterial (A-A) gradients were determined by the method described by Riley and Lilienthal (*Am J Physiol* 147:191, 1946) and compared with values obtained by Dill and Penrod's method (*J Applied Physiol* 1:409, 1948). The latter were obtained by subtracting the sum of the arterial pO_2 , pCO_2 , pH_2O , and pN_2 from the prevailing barometric pressure. In certain patients Bohr's method of graphic integration was used to determine the diffusion coefficient for oxygen, and from this procedure the Bohr A-A gradient was obtained from the final ΔpO_2 . The similarity between the Riley-Lilienthal and Dill-Penrod methods was shown in normal persons, where the mean A-A gradient was 9 mm Hg (Riley-Lilienthal), and 10 mm Hg (Dill-Penrod). When these 2 methods were compared in cases with emphysema, pulmonary vascular disease, and cirrhosis of the liver, this close similarity was not as pronounced. The Dill-Penrod method yielded a 5 mm Hg higher value. In this group, the final ΔpO_2 in the Bohr integration resulted in an A-A gradient

intermediate between these 2 values. Further comparison of the Dill-Penrod and Riley-Lilienthal methods in other patients showed a slightly better agreement. The Dill-Penrod values were still 3 mm Hg higher on the average than the Riley-Lilienthal values. Possible reasons for these discrepancies were presented and it was pointed out that the Dill-Penrod method, although apparently less accurate, does give one much useful information with only a single analysis of arterial blood.

Influence of tonic contracture upon the composition of mammalian skeletal muscle, especially upon its electrolyte content ERNST FISCHER AND HELEN V. SKOWLUND * *Dept of Physiology, Med College of Virginia, Richmond*

The electrolyte content of left and right identical normal rabbit muscles shows little difference. The chloride content of different anatomical muscles varies more than 15%, while the values for potassium and sodium differ about 5% and 10% respectively. However, if one calculates the K and Na concentrations existing inside the muscle fibers, assuming that chloride is restricted to the tissue spaces, rather uniform K and Na values are found for different muscles. The early contracture of neurological origin developing in tenotomized gastrocnemii, which can be prevented by denervation, decreases K content much more than can be explained by the relative increase in connective tissue caused by the higher rate of atrophy. Na enters the muscle fibers to a large extent and replaces the lost K. The muscle membranes become rather permeable for Cl, and finally about 20% of the total Cl is apparently located inside the fibers. Experiments with the radioisotope K^{42} revealed that contracture increases considerably the permeability of the muscle membranes for K. Besides the changes in electrolytes, early contracture causes a decrease in total protein concentration, a deterioration of the specific muscle proteins myogen and mvosin, and a decrease in the aldolase and adenosinetriphosphatase activity quotient of the isolated myogen and myosin respectively.

Internal water exchange in normal and hypotensive dogs M. J. FOGELMAN AND P. O. 'B' MONTGOMERY (introduced by CARL A. MOYER) *Dept of Exper Surgery, Southwestern Med School of The Univ of Texas, Dallas*

A study was undertaken to determine the rates of exchange of water between the vascular and extra-vascular spaces using D_2O as a tracer. The studies were designed so that the differential rates of water movement were determined in each dog both under normal conditions and following subjection to a constant hypotensive level induced by bleeding. D_2O was determined by a

modification of the falling-drop method on purified samples of lyophilized whole blood. Plasma volume was determined with T-1824. A known amount of D_2O in isotonic saline (approximately 0.5 cc/kg/bw) was injected intravenously and heparinized arterial blood samples drawn at frequent and close intervals for periods ranging from 40-90 minutes. Time concentration curves were constructed and the equations for these curves derived according to the method of Flexner, *et al* (*Symposia on Quant Biol* 13: 88, 1948). The calculations reveal that in the normal dog approximately 72% of total blood water moves extravascularly/min. Following subsection to a constant hypotensive level of approximately 75 mm Hg mean arterial pressure an average of 41% of total blood water passes across the vascular membrane/min. Further calculations reveal that in the normal dog approximately 23% of total body water moves across the vascular membrane in each direction/min, and that in the animal subjected to hypotension approximately 12% of the total body water moves across the vascular membrane/min. The reduction in exchange rates of D_2O following hemorrhage are tentatively ascribed to the reduction in the functional diffusion area induced by the loss of blood. The significance of these results and their relationship to water and electrolyte movement in various conditions will be discussed.

Application of a technique for sampling respiratory gases in non-cooperative subjects C A FORSANDER (introduced by C WHITE) *Dept of Physiology, Univ of Pennsylvania School of Medicine, Philadelphia*

By applying an oral suction technique developed for the collection of samples of alveolar air it has been possible to obtain estimations of the CO_2 tension of the mixed venous blood entering the lungs, within 6-12 seconds of breathing mixtures of CO_2 and oxygen, and without interfering with the respiratory pattern. Reproducible levels of CO_2 equilibrium have been found at 6, 15, 21 and 24 seconds. In a basal subject breathing 10/min, the CO_2 tension of the alveolar air after one normal breath of gas mixture was 46 mm Hg, after 2 breaths 48.8 mm Hg, 3 breaths 49.5 mm Hg, 4 breaths 53 mm Hg. The rise in CO_2 tension after 12 seconds is interpreted as being due to recirculation. Before 12 seconds the rise is due either to delay in mixing of the inspired gas with the residual air, or may reflect the volume of the pulmonary blood flow. These results are demonstrated if the deadspace air is removed before introduction of gas mixtures and before sampling.

'Resonance' of muscle to central stimulation

A A FOSTER (introduced by HANS LOWEN-

BACH) *Dept of Anatomy, Duke Univ, Durham, N C*

It has been previously demonstrated and we have confirmed the gross fact that frequencies below approximately 17 stimuli/sec applied to the proper point in motor cortex of a dog, under sodium pentobarbital (Nembutal), produce extension of the contralateral hind limb. Frequencies from 17-21 s p s produce flexion. Frequencies just below 34 s p s produce extension and good flexion results from 34-37 stimuli/sec. Grossly these phenomena indicate resonance of flexors to 17 and 34 stimuli/sec. The distal branch only of the nerve to that double muscle, the semitendinosus, was cut and a neurogram taken distal to that cut. The sensory responses to the twitching of the extensor portion followed one to one up to 17 s p s but became irregular thereafter. Just below 34 the response was again regular but only to alternate stimuli. These responses again failed to pass 17 as the stimuli passed 34. The extensors apparently can follow up to 21 or one half 42 stimuli/sec. These 'drop out points' rise and fall slightly with rise and fall of intensity of stimulation. This indicates a relaxation oscillator type of action. In general tetany, extension is the rule due to the greater strength of the extensors. It is therefore concluded that the normal pattern is extension but between 17 and 21 s p s the extensors are not responding to every stimulus while the flexors still are and so the latter prevail over their antagonists. The flexors enjoy a similar advantage in the band just above 34 stimuli/sec.

Effect of lithium on the renal excretion of potassium JAMES G FOULKS,* GILBERT H MUDGE* AND ALFRED GILMAN *Dept of Pharmacology, Columbia Univ College of Physicians and Surgeons, New York City*

The renal excretion of electrolyte during the infusion of isotonic lithium chloride was studied in dogs under barbiturate anesthesia. Cations were determined by direct flame photometry. The volume distribution of lithium varied with the rate and duration of the lithium infusion, but uniformly exceeded the extra-cellular fluid volume. The calculated lithium space was 30 to 60% of the body weight. The proportion of filtered lithium excreted in the urine was relatively constant over a wide range of serum lithium concentrations (1-25 mEq/l), lithium clearances averaged 30% of the filtration rate (range 18-48%). The excretion of lithium was not altered significantly by mercurial diuretics. The infusion of lithium consistently elevated rates of potassium (K) excretion. At serum lithium concentrations of 4-5 mEq/l, K clearances of 50-80% of filtration rate were generally observed. K clearances in excess of filtration rate were promptly obtained when

lithium infusion was combined with a moderate osmotic (S_2O_3) diuresis. Lithium induced increments in the rate of K excretion are interpreted as representing tubular K secretion, since they are markedly reduced by mercurials. Simultaneous infusion of lithium and K failed to reveal evidence of competitive excretion.

Measurement of ventilatory dead space in subjects with uneven pulmonary ventilation WARD S FOWLER (introduced by J H COMROE, JR.) *Dept of Physiology and Pharmacology, Univ of Pennsylvania, Graduate School of Medicine, Philadelphia*

Measurement of ventilatory dead space requires identification of alveolar gas. The N_2 concentration—expired volume curve of gas expired after one inspiration of O_2 by normal subjects and patients with pulmonary disease—shows three phases. N_2 concentration successively 1) equals inspired concentration, 2) changes in an S-shaped fashion, 3) is rectilinear. Previous studies of normal subjects indicate that phase 3 is alveolar gas, following dead space wash-out (phases 1 and 2). In certain patients, the intersection of phases 2 and 3 is less definite, since the slope of the last part of the S-curve changes little and approaches the slope of phase 3. When such patients inspired O_2 followed without interruption by air, the sign of slopes of phases 2 and 3 were dissimilar, clarifying the point of intersection. The expired volumes corresponding to the intersection point were similar with inhalations of O_2 alone, or O_2 air. Such studies indicate that after maximal inspiration expired volume required for patients with pulmonary disease to wash out the dead space is not greater than normal, and that a valid alveolar concentration can be obtained for measurement of ventilatory dead space in patients if their expirations show a third phase which is linear, even though sloping (i.e. expired alveolar gas composition varies).

Mechanical impedance of surface of human body and its relation to elastic properties of skeletal muscle ERNST K FRANKE (introduced by H M SWEENEY) *Aero Med Lab, Air Materiel Command, Wright-Patterson Air Force Base, Dayton, Ohio*

In order to investigate the mechanical behavior of the human body surface when brought in contact with various vibrating structures, measurements were made with a small, sinusoidally vibrating piston applied to the body surface. From the vibratory forces exerted by the piston on the body, measured by means of a variable reluctance pressure gauge, the mechanical response of the body was calculated in terms of impedances, a procedure widely used in acoustics. It is shown that the results justify establishing a simple

harmonic vibrating system with lumped constants as a model of the mechanical behavior of the body surface. The constants of this model are calculated and their meaning is discussed. In order to investigate the nonlinear characteristics of muscle, some further measurements were made to determine the stiffness constant as a function of the pressure used to apply the piston. From the results obtained, the equation of motion of a hammer hitting the body surface was established. In this way it was possible to compare the results of the impedance measurements with measurements of contact time and rebound obtained by a ballistic method recently published by E Simonson *et al* (*J Applied Physiol* 1:512, 1949).

Propagation of surface waves over the human body ERNST K FRANKE, HANS OESTREICHER AND WOLF W VON WITTERN (introduced by H M SWEENEY) *Aero Med Lab, Air Materiel Command, Wright-Patterson Air Force Base, Dayton, Ohio*

A well established wave pattern appears on a body surface, such as that overlying the rectus femoris, when the surface is in firm contact with and driven by a small piston (diameter 1 in.) at frequencies near 100 cps. This pattern is easily observed and photographed by stroboscopic light. The wavelength was determined by measuring, through several wavelengths, the change of phase of the deflection as a function of distance from the center of the piston. For this purpose the vibrations were detected by a capacitive device which used the body as one electrode and a small disc at a suitable distance as the other. This arrangement did not disturb the wave propagation. Changes of capacity due to the vibrations are converted into electrical signals by operating the condenser in a high frequency resonant circuit. The propagation velocity was found to be constant at about 160 cm/sec in the frequency range 15–150 cps. When the amplitude of the exciting piston is held constant, 1) at any frequency the wave amplitude varies inversely with the square of the distance, and 2) at any distance the wave amplitude varies inversely with frequency. Theoretical considerations concerning the wave propagation in viscous-elastic media give a general picture of the mechanism of the waves and their relation to the elastic properties of the medium. Such considerations show also that the waves are essentially shear waves in this frequency range.

Descriptive analysis of vasomotor responses in footpad of the dog F E FRANKE, W C RANDALL, J W COX,* W F ALEXANDER* AND A B HERTZMAN *Depts of Physiology and Anatomy, St Louis Univ School of Medicine, St Louis, Mo*

Reflex vasoconstrictor responses in the footpad

of the dog as recorded by the photoelectric plethysmograph were compared with those responses induced by direct faradic stimulation of the sympathetic chain. In many constrictor responses, a decrease in amplitude of the volume pulse preceded the reduction in volume of the part by 0.5 to 5.0 seconds. In some responses, the decrease in volume pulse and blood volume occurred almost simultaneously. The frequently observed striking differences in onset of these two phases of the vasoconstrictor responses strongly suggest the operation of separate arteriomotor and venomotor mechanisms. After cessation of a strong stimulating current, the vascular constriction persisted for as long as 20-30 seconds before relaxation of the vessels first became apparent. Recovery was marked first by an increasing amplitude of the volume pulse followed by a progressive rise in volume of the part. In all cases the recovery was slow, and in many instances following constriction to complete obliteration of the pulse, the total recovery period extended over 3-5 minutes. The latent period from the time of stimulation to the appearance of the first phase of the constriction was approximately 0.5 to 1.0 second longer in the reflex responses as compared with the response to direct stimulation of the chain, and in both instances was several times as long as in the somatic reflex arc.

Effect of physical factors on radiosodium clearance in dogs FREDERICK R. FRANKE,* JOSEPH B. BOATMAN,* ROBERT S. GEORGE* AND CAMPBELL MOSES *Addison H. Gibson Lab., Univ. of Pittsburgh School of Medicine, Pittsburgh, Penna.*

The clearance of radiosodium from injected sites under varying conditions has been studied in a series of 31 experiments on dogs under pentobarbital sodium anesthesia. Injections of 0.25 to 1.0 cc. of saline carrying approximately 5.0 microcuries of Na^{24} were made subcutaneously and intramuscularly. The decline of activity over the injected area was measured with a shielded thin window Geiger-Mueller tube coupled to an autoscaler. Decline of activity was expressed as slope constant (clearance constant) based on change in activity per unit time. Control observations have been made and clearance constants under various conditions have been determined. The mean intramuscular clearance constant in a series of 27 determinations was 0.0473, the mean subcutaneous clearance constant of 5 experiments, 0.0071. Variations in muscle clearance have been produced by local application to the injected site of ice-salt mixtures and radiant heat. Alteration of the clearance constant to almost zero was seen with external interruption of venous return by applications of an abdominal pressure cuff. The addition

of hyaluronidase to subcutaneous injections produced an increased clearance constant of almost sixfold over the subcutaneous control. Preliminary studies support the view that clearance of radio-sodium from intramuscular sites may be made a quantitative test for detection of early congestive failure.

Direct measurement of I^{131} thyroid gland uptake and turnover in relation to thyroid function in normal and pathologic states A. STONE FREEDBERG, DAVID L. CHAMOVITZ AND ALVIN L. URELES (introduced by H. L. BLUMGART) *Medical Research Labs., Beth Israel Hospital and Dept. of Medicine, Harvard Med. School, Boston, Mass.*

The successful development of a quantitative method (FREEDBERG, URELES AND VANDILLA, *Federation Proc.* 8:50, 1949) for the measurement of thyroid I^{131} radiation has permitted more exact study of thyroid gland function in respect to I^{131} metabolism in man. Utilizing this 4 Geiger-Mueller tube method, uptake and turnover of I^{131} in the thyroid gland following oral doses of 150 μc , carrier-free, have been studied in 171 patients. Evaluation of thyroid function was made by clinical criteria, basal metabolic rate, serum cholesterol and, in some instances, serum protein-bound iodine. In 32 normal euthyroid subjects (Group A) the 24-hour uptake averaged 29% (S.D. 4.8), in 27 euthyroid patients with nodular goiters (Group B), 36% (S.D. 11.0). In 17 patients (Group C), euthyroid for 5 to 39 (av. 19) months after I^{131} therapy for hyperthyroidism, the 24-hour uptake averaged 38% (S.D. 11.3). The differences between the means of Groups A and B, and A and C are statistically significant. In 48 thyrotoxic patients (Group D) the 24-hour uptake averaged 69% (S.D. 13.1). In 7 patients with mild hypothyroidism the 24-hour uptake averaged 18% (range 13-23), in 10 patients with marked hypothyroidism, 8% (range 4-13). The biologic half-life (turnover) in Group A was 7.5 (S.D. 0.9) days, Group B, 7.5 (S.D. 0.5), Group C, 4.7 (S.D. 0.8) and Group D, 5.7 (S.D. 1.1). In 18 patients, persistently hyperthyroid after I^{131} therapy (Group E), the turnover was 4.3 (S.D. 1.1) days. The differences between the means of all groups, except A and B, and C and E, are statistically significant. The influence of various drugs and pathologic states are described.

Comparative study of ascorbic acid levels in gastric secretion, blood, urine and saliva JOSEPH T. FREEMAN* AND ROBERTA HAFKES BRING *Depts. of Medicine and Physiology, Woman's Med. College of Pennsylvania, Philadelphia, Penna.*

Ascorbic acid determinations of fractional gastric specimens, whole blood, saliva and urine

(24-hour) were made on 100 apparently normal individuals. The purpose was to establish a standard for comparative studies of intrinsic gastrointestinal diseases. All determinations were on individuals fasted 15 hours and with a low vitamin C intake for the preceding 24 hours. Roe and Kuether's method was used (*J Biol Chem* 147:399, 1943). The average gastric vitamin C was 1.04 mg %, range 0.04-3.9 mg %. The average whole blood C was 1.00 mg %, range 0.26-2.1 mg %, salivary content was 0.10 mg %, range 0-0.36 mg %, and the urine was 1.62 mg % with a range of 0-9 mg %. The average 24-hour urine excretion was 15.00 mg with a range of 0-80 mg. Allowing a deviation of 0.05 mg, there was a correlation between blood and gastric vitamin C in only 4 cases, in 59 cases the blood ascorbic level was higher, while in 33 the gastric ascorbic level was higher. No apparent relationship was noted between the blood gastric ascorbic content and free or total acidity. The same conclusion holds for these 2 measurements when correlated with the salivary vitamin C content and the 24-hour urinary output of vitamin C. The evaluation of all possible correlations of these figures in normal individuals suggests that ascorbic acid in gastric juice may be a function of gastric cells. Application of these results is already being made in various types of abnormal conditions.

Functional regeneration after nerve root transplantation in the guinea baboon. L. W. FREEMAN, J. C. FINNERAN* AND L. R. RADIGAN*. *Labs of Surgical Research, Indiana Univ School of Medicine, Indianapolis, and Labs of Physiology and Surgery, Yale Univ School of Medicine, New Haven, Conn.*

The vigorous capacity for regeneration demonstrated by spinal nerve roots has led to a preliminary investigation of the possibilities of nerve root transplantation. The male Guinea baboon characteristically maintains a relatively constant penile erection. After sacral nerve root denervation intradurally this power is lost. Bilateral lumbar sympathectomy in two preparations has failed to alter penile erection. In five preparations anastomosis of the coccygeal (1), third lumbar (1) or fourth lumbar (3) nerve roots to the sacral innervation has been followed in a period of approximately 8 months by a return of erectile ability. Stimulation experiments in one animal definitely established the neural continuity of the anastomosed nerve roots. Anatomic specimens of all have shown neural continuity.

Chemical changes occurring during symphyseal relaxation. EDWARD H. FRIEDEN* AND F. L. HISAW. *Biological Labs, Harvard Univ, Cambridge, Mass.*

Relaxation of the pelvic symphysis of the

guinea pig is accompanied by a considerable change in the weight of the symphysis. This weight increase, which in extreme cases may be 4- or 5-fold, appears to be due largely to infiltration of plasma, together with some extravasation of whole blood. The available histological evidence suggests alteration in the state of the ground substance as well as changes in the collagenous matrix of the tissue. In a search for clues to the mechanism of the action of relaxin, comparative chemical and enzymatic analyses have been made of control and relaxed (pregnant rabbit serum or purified relaxin) guinea pig symphyses. Assays for phosphatase and glucuronidase reveal no differences significant enough to implicate these enzymes in the relaxation process. Tissue analyses of the distribution of N, hydrolyzable reducing groups, and hydrolyzable hexoseamine indicate little, if any, recognizable effect upon a polysaccharide or mucoprotein substrate. The most significant finding has been that the ratio of collagen N to total insoluble N decreases during relaxation. Collagen, as determined by alkali extraction or tryptic digestion, constitutes from 60-80% of the total residue protein of the unrelaxed symphysis. In the relaxed animal, the range is 40-70%, in comparable experiments the range of overlap is small, and the decrease in collagen may be correlated with the extent of relaxation.

Purification and properties of relaxin. EDWARD H. FRIEDEN* AND F. L. HISAW. *Biological Labs, Harvard Univ, Cambridge, Mass.*

The problem of the preparation and purification of relaxin has been re-examined. Aqueous saline or acid extracts of pregnant sow ovaries contain relaxin in combined form, as evidenced by the fact that the physical and physiological properties of the active fraction vary with the extent of purification. The combination appears to be a relatively labile one, and may readily be split by the addition of alcohol. Subsequent purification is effected by a combination of isoelectric and ethanol precipitations. The most active fractions will induce good symphyseal relaxation in the guinea pig at a level of about 10 micrograms, corresponding to a purification of 500-1000-fold compared with the original fresh tissue. There is evidence that this preparation represents the hormone in nearly pure form. Purified relaxin is a relatively low molecular weight protein, as indicated by dialysis studies and positive reactions to common protein reagents, and is quite stable. It contains 12.7% N and 10.5% reducing sugar upon hydrolysis, about half the latter is hexoseamine.

Histochemical differentiation of substrate specific alkaline phosphatases in tissue of the rat. JONAS S. FRIEDENWALD AND GERTRUDE D. MAENGWYN-DAVIES*. *Wilmer Ophthalmological*

(24-hour) were made on 100 apparently normal individuals. The purpose was to establish a standard for comparative studies of intrinsic gastrointestinal diseases. Histochemical differentiation of substrate specific alkaline phosphatases in tissue of the rat. JONAS S. FRIEDENWALD AND GERTRUDE D. MAENGWYN-DAVIES* *Wilmer Ophthalmological*

Inst, Johns Hopkins Univ and Hospital, Baltimore, Md

In order to study the tissue localization of various substrate specific alkaline phosphatases, we have applied an adaptation of Gomori's technique (Proc Soc Exper Biol & Med 42: 21, 1939)

to fresh frozen tissue sections. In such sections many enzymes tend to diffuse. Good localization was obtained when working with a substrate solution half saturated for sodium acetate, and fully saturated for calcium phosphate. After incubation the acetate was washed out with a water-alcohol-calcium chloride mixture, and the enzymatically deposited calcium phosphate converted to cobalt sulfide. These studies were undertaken with the following substrates: glycerophosphate, glucose-1-phosphate, fructose 6 phosphate, hexose diphosphate, calcium β -naphthylphosphate, and muscle adenosine-triphosphate. All substrates were employed at the same molarity. Evidence for the substrate specificity of a number of alkaline phosphatases will be presented on the basis of the effects of different inhibitors and activators, and of variations in diffusibility and organ distribution

Transfer of proteins tagged with radioactive iodine

from plasma into lymph HERBERT D. FREEDLANDER, PARKER BIRROD, HOWARD J. CURTIS AND GEORGE R. MENEZLY (introduced by WALTER E. GARREY) Radiobiology Unit of Thayer Veterans Administration Hospital and Dept of Physiology and Medicine of Vanderbilt Univ School of Medicine, Nashville, Tenn

Small quantities of dog plasma were tagged with I-131. When introduced i.v. into dogs this protein disappears relatively slowly during the first few hours of highest concentration. The rate of fall in concentration varies from dog to dog. From 15-40% may disappear from the circulation within 2-3 hours. The tagged protein soon appears in the lymph. Within 15-20 minutes, sizeable amounts of radioactive protein can be collected from the thoracic duct lymph. In the paw the slow flow of lymph makes the time for collecting measurable quantities longer than is the case with the thoracic duct lymph, however, within 30 minutes a considerable amount can be measured in lymph collected from the hind leg. The concentration of the labelled material in the lymph increases with time so that in this fluid the concentration approaches 25-50% that of the plasma in about 2-3 hours. The amount of labelled protein/mg of protein nitrogen in the paw lymph differs from that found in the lymph collected from the thoracic duct. This difference is not striking in all animals examined, but where it occurs the tagged protein/mg of protein nitrogen is greater in the lymph collected from the thoracic duct. These

results suggest that the protein in this experiment is transferred across the capillary membrane more rapidly than previously thought for plasma proteins in the capillaries of the gut and liver as well as in the excretories

Absence of anti-ulcer factor from urine of patients with duodenal ulcer AL H. F. FRIDMAN, Dept of Physiology, Jefferson Med College, Philadelphia, Pa

A diet was formulated which consisted essentially of an enzymatic digest of purified protein fortified with tryptophane. Supplements of purified dextrose, lipids, vitamins and salts were added as needed. (1) This diet proved ulcerogenic for mice. The animals lost weight progressively, developed diarrhea with bloody stool, and assumed a posture suggestive of peritoneal irritation. The maximum survival time on this diet was 12 days. At autopsy, the gastric mucosa was always found to have ulcerative lesions. These ranged in severity from mucosal erosions to apparently penetrating ulcers. Alucosal bleeding and the presence of free blood were often noted in the small intestine, usually in the duodenum and terminal ileum. (2) Addition to this diet of crude extracts of urine from healthy men protected female mice, but not male mice, from developing gastrointestinal ulcerations and prolonged their survival time. The maximum survival time for female mice was 23 days and for male mice 12 days. (3) Crude extracts of urine from men with duodenal ulcer did not exert any protective action against ulcer development in either male or female mice, and failed to prolong life (maximum survival time, 12 days). (4) Protection against ulcer development and prolongation of survival time (up to 46 days) were noted when crude extracts of hog duodenal mucosa were added to the diet. Crude extracts of hog duodenal mucosa, purified extracts of hog intestinal mucosa ('enterogastrene'), and crude extracts of pork muscle were without anti-ulcer effects. Crystalline vitamin B₁₂ was also without effect. (5) Studies on the nature of the anti-ulcer factor and the effects of various fractions of normal male urine on normal and castrate female mice are continuing.

Effect of ultrasound on nervous tissues

W J WULFE Univ of Illinois, Urbana AND V J FRY

Ultrasound was applied to peripheral nerve, grayish ventral nerve cord and spinal cord of eel-frog. Ultrasound was without effect on excitability, wave form of the spike potential or propagation velocity of peripheral nerve, even after prolonged exposures. The exposed grayish ventral nerve cord exposed to ultrasound exhibited a reduction of spontaneous activity after several seconds exposure and recovered its original activity about one minute after the ultrasound was

turned off Frogs positioned so that ultrasound was incident on the dorsal surface over the lumbar enlargement evidenced paralysis of the hind legs after 4.3 seconds exposure (at room temperature) and produced paralysis after 7.3 seconds exposure (at $1^{\circ}\text{--}2^{\circ}\text{C}$) Histological examination of the sciatic nerves showed extensive degeneration of nerves and examination of the spinal cord showed marked pathology of the lower motor neurones Temperature measurements indicated that peripheral nerve and crayfish ventral nerve cord exhibited a maximal rise of $1^{\circ}\text{--}2^{\circ}\text{C}$ The spinal cord of intact frogs exhibited temperature rises as great as 40°C By using frogs cooled to 1°C and reducing the ultrasound exposure to two 4.3-second pulses interrupted by 4-minute cooling off period, it was demonstrated that temperature rises did not exceed 15°C and that paralysis of the hind legs occurred during the second 4.3-second exposure Similar experiments on frogs (room temperature) indicated paralysis upon exposure to ultrasound pulses of 0.080 second, delivered at a rate of 2.0/sec and no paralysis upon exposure to sound pulses of 0.010 second delivered at a rate of 20/sec, yet the latter procedure produced a higher cord temperature than the former

Characteristic response of isolated frog skin potential to neurohypophyseal principles and its relation to transport of sodium and water
 FREDERICK A. FUHRMAN AND HANS H. USSING *
Lab of Zoophysiology, Univ of Copenhagen, Denmark, and Dept of Physiology, Stanford Univ School of Medicine, Stanford, Calif

Previous experiments of one of us have indicated a close correlation between the potential difference and the sodium transport across the isolated frog skin The present experiments which deal with the effect of neurohypophyseal principles on Na transport, water transport and P D across the isolated skin of *Rana esculenta*, bear out very clearly the above mentioned relationship The apparatus used has been described previously (USSING *Acta Physiol Scandinav* 17:1, 1949) Na influx and outflux were determined with Na^{24} , and the water uptake was calculated from the radioactivity measurements Commercially prepared fractions of vasopressor and oxytocic principles, as well as whole powdered posterior lobe of the blue whale, markedly increased the P D This increase in P D varied inversely with initial P D, but within wide limits was nearly independent of hormone dose Both with and without hormone the influx and outflux of Na showed a nearly linear increase with increasing P D The influx was always higher than the outflux and the net Na influx increased with increasing P D After addition of the hormones, however, a higher P D was obtained for a given Na influx Thus, after

hormone addition, more work has to be done to transport Na actively against the electrical force Increase in net uptake of water from the outside solution occurred after addition of the hormones

Blood flow in transilluminated membranes after stasis and under pathological and traumatic conditions (motion picture)
 GEORGE P. FULTON AND ROBERT P. AKERS (introduced by LELAND C. WYMAN) *Dept of Biology, Boston Univ, Boston, Mass*

Motion picture records were edited to demonstrate the characteristics of the circulation in the transilluminated retrolingual membrane of the frog and the cheek pouch of the hamster under pathological and traumatic conditions, and after stasis In hamsters with advanced tumors of carcinogenic origin, the blood appears thin with relatively few erythrocytes, but vast numbers of leucocytes apparent even on the walls of the arterioles Numerous white cells are also seen in hamsters with a staphylococcus infection In both cases erythrocytes are seen at times in groups separated by plasma and white cells, resembling sludged blood However, individual components of the group can be separated readily by manipulation of the vessel wall with a microprobe Pictures taken with reflected light at low power ($\times 54$, $\times 90$) suggest sludged blood, but those taken with transmitted light at higher power ($\times 200$), accompanied by microprobing, indicate that the erythrocytes are not agglutinated The circulation is shown in animals under severe traumatic conditions Erythrocytes are unagglutinated in prolonged stasis as shown by microprobing of vessels packed for several days with noncirculating red cells and by the escape of the erythrocytes as individual corpuscles from vessels severed with a microknife Platelet accumulation is shown following release from venous occlusion in the cheek pouch Groups of platelets break off continuously from the accumulating mass and circulate Additional platelets adhere at the same point In larger vessels, blood flow forms complex channels through the adherent mass of platelets

Food deprivation and sexual reflexes
 W. HORSLEY GANTT *Pavlovian Lab, Phipps Clinic, Johns Hopkins Univ, Baltimore, Md*

Sexual conditional reflexes (crs) were formed in 3 male dogs (Poco, age 7, Chester, 4, Choptank, 4) These Chesapeake Bay dogs formed sexual crs quickly (to stimulation of the external genitalia) and retained them for at least 7 months without reinforcement All male dogs do not form overt sexual reflexes under laboratory conditions In some dogs where there is no motor sexual cr (erection), a cardiac component gives evidence of sexual cr formation (ROBINSON AND GANTT *Bull Johns Hopkins Hospital* 80:231, 1947) The

Synergism of thromboplastin extracts from brain and lung CLIFFORD F GERBER* AND ERNEST W BLANCHARD *Research Labs, Schieffelin and Co, New York City*

When saline extracts of brain and lung are combined the resulting mixture exhibits greater thromboplastic potency than either of the original extracts. The same synergism is obtained if a saline extract is prepared from a mixture of the two tissues. Identical potencies are obtained in all proportions of the tissues, from 70% brain plus 30% lung to 30% brain plus 70% lung. The synergism was given by brain and lung mixture from the several species used and by dried tissues as well as fresh. There are time and temperature factors for the full development of the synergism indicating that a definite interaction occurs. Extracts of the two tissues were made separately. Each extract was then subjected to ether extraction. The ethereal solutions were added to the heterologous tissue extract. The lung saline extract plus brain ethereal solution showed almost complete restoration of activity. The brain saline extract was unaffected by the addition of lung ethereal solution. This experiment indicated that neither tissue is a complete thromboplastin and that excess lipid is supplied by the brain extract to the lung extract.

Further observations on metabolic fate of chloramphenicol (Chloromycetin) ANTHONY J GLAZKO, WESLEY A DILL* AND LORETTA M WOLF* *Research Laboratories, Parke, Davis and Company, Detroit, Michigan*

Earlier reports from this laboratory have shown that chloramphenicol is converted in the body to a microbiologically inactive monoglucuronide derivative which is excreted in the urine and bile along with small amounts of unchanged chloramphenicol. Further studies have been made on the metabolic fate of this glucuronide in the rat, using material isolated from human urine. Studies with isolated intestinal loops in the rats indicate that the glucuronide as such is poorly absorbed from the intestinal tract. Parenteral administration results in the appearance of chloramphenicol as well as inactive nitro compounds in the urine, probably due to enzymatic hydrolysis of the conjugate in the tissues prior to absorption. Similar activation has already been demonstrated *in vitro* with β -glucuronidase. Antibiotic activity is also found in the caecum and large intestine of the rat after administration of the glucuronide derivative, due to the hydrolytic action of bacterial enzymes. A portion of the liberated chloramphenicol is then reabsorbed. This process may contribute to the maintenance of effective antibiotic levels in the blood and tissues, providing a cyclic mechanism for return of a portion of the metab-

olized drug to the body in an active form. In addition to the activation process, large quantities of aromatic amines are produced by bacterial reduction of the nitro group in the intestinal tract of lower animals.

The effect of clothing on the physiological adjustments of human beings to sudden change in environment N GLICKMAN, T INOUE,* R W KEETON, S E TELSER* AND M K FAHNESTOCK* *Dept of Medicine, Univ of Ill College of Medicine, Chicago, and Dept of Mechanical Engineering, Univ of Ill, Urbana*

Physiological adjustments to sudden changes in ambient environment of 7 subjects wearing standard summer weight clothing (SC1) were compared with those of 10 subjects wearing a 90% cotton full length union suit (US). Exposure for one hour in the comfortable room (CR1) at 24.4°C with water vapor (VP) of 9.2 and 24.4 kilodynes/cm² was followed by one or two hours in the hot room (HR) at 37°C with water vapor of 41.1 kilodynes/cm², then re-entry into the comfortable room (CR2) for one hour. All data were analyzed statistically. The SC1 with its several layers of material compared with the single layered US effected only slight differences in the physiological adjustments of the subjects, these occurred primarily during the first 10 minutes of exposure to the changes in environment. The buffering effect of clothing was evident on entering the HR and on re-entering CR2, upon entering the HR the MT, and pulse rate increased less for the SC1 group than for the US group and decreased less upon re-entering CR2. Subsequent changes in these and other factors were similar for both groups, except that during the second hour in the HR the MT, and T_{re} increased more for the SC1 group. Greater differences of ambient temperature undoubtedly would have shown the effect of clothing more clearly. Evaporative weight loss, thermal sensations, clothing temperatures (MT_{cl}), gradients between MT, and MT_{cl}, and the rapidity and magnitude of certain adjustments are discussed.

Osmotic behavior of isolated nuclei LESTER GOLDSTEIN AND CLIFFORD V HARDING (introduced by L V HEILBRUNN) *Dept of Zoology, Univ of Pennsylvania, Philadelphia*

Nuclei from the oocytes of the frog, *Rana pipiens*, were isolated by hand, and the osmotic behavior of these large nuclei was then studied by following the volume changes after immersion in various solutions. Nuclei from full-grown oocytes and from small, unpigmented oocytes were compared. The nuclei from oocytes of both stages were found to be freely permeable to salts and sugars, similar results with the large nuclei have recently been reported by Callan. The rates of penetration of Ca-free frog Ringer's solution and 1.5 molal

sucrose solution across the membranes of the younger (smaller) nuclei were found to be greater than across the membranes of the older (larger) nuclei. Egg albumin, however, did not penetrate the membrane and it was found possible to obtain an isotonic solution. We can therefore determine the colloid osmotic pressure of the nucleoplasm at the two different stages of oöcyte development. Results indicate that the colloid osmotic pressure of the nucleoplasm within the smaller oöcytes is significantly greater than in the larger oöcytes. In comparing nuclei of small and large oöcytes, the observed difference in rates of penetration of salt and sugar solutions is probably due, at least in part, to this difference in colloid osmotic pressure, and it may also be due in part to permeability differences. This latter possibility is now being investigated.

Myocardial glucose, lactate and pyruvate metabolism of normal and failing hearts studied by coronary venous catheterization in man. WALTER T. GOODALE, ROBERT E. OLSON* AND DONALD B. HACKEL* *Peter Bent Brigham Hospital, Dept of Medicine, Harvard Med School, and Dept of Nutrition, Harvard School of Public Health, Boston, Mass*

Studies on 9 subjects revealed significant differences between arterial and coronary venous blood concentrations of glucose, lactate and pyruvate, reflecting extraction and presumptive utilization of these metabolites by the myocardium. In terms of coronary arteriovenous difference, extraction of each metabolite was related directly to its own arterial level. The slopes obtained by plotting extraction against arterial level for each metabolite compared closely with those obtained in intact dogs by similar techniques, except that glucose values in man showed much less scatter. At average non-fasting arterial glucose, lactate and pyruvate levels of 103, 7.5 and 1.3 mg % respectively, the average coronary arteriovenous differences were 10.7, 2.7 and 0.4 mg % respectively. Oxidation of this quantity of substrate could account for 90-100% of the simultaneous oxygen extraction. At low fasting arterial levels, glucose, lactate and pyruvate extractions were small, suggesting a dependance of the myocardium upon other substrates during fasting. Three patients with multivalvular disease in congestive failure with low cardiac outputs, showed low coronary venous oxygen saturations of 10, 17 and 18% (normal 29-38%, 7 cases). Myocardial glucose, lactate and pyruvate utilization was normal, indicating a maintenance of a normal aerobic oxidation pattern. Related studies on similar cases with Bing *et al* showed that left ventricular blood flow/100 gm of myocardium was normal or slightly increased, with increased total flow by virtue of cardiac hypertrophy. Thus there

appears to be no defect in oxidative energy production, but rather a failure to convert this energy to effective mechanical work.

Changes in muscle phosphorylase and hexokinase activities produced by inanition in the rat. E. S. GORANSON, NANCY M. DANOFF AND ELIZABETH F. PURDIE (introduced by E. A. SELLERS) *Dept of Physiology, University of Toronto, Toronto, Canada*

It has previously been reported that the muscle phosphorylase activity of rats increased after a short period of starvation and that this increase was reversed by refeeding (K. LUNDBAEK AND E. S. GORANSON *Acta physiol Scandinav* 17: 280, 1949). More recent studies show a reversal of this increase in phosphorylase activity on refeeding with carbohydrate but not on refeeding with an isocaloric fat diet after a period of inanition. A reversal of activity was also observed one hour after the simultaneous administration of glucose and insulin but not after the injection of insulin alone. Glucose per se, one hour after its injection into fasted rats, had a variable effect in reversing the activity of the enzyme. While an increase in muscle phosphorylase activity was observed after a period of inanition, starvation produced a significant lowering in muscle hexokinase activity. The possible significance of these changes will be discussed.

The adrenal gland and hemopoiesis in the rat. ALBERT S. GORDON AND SAM J. PILIERO* *Dept of Biology, Washington Square College of Arts and Science, New York Univ., New York City*

Female rats (140-170 gm) were adrenalectomized and maintained on 1% saline given as drinking water. Hematologic determinations were made at 7-10 day intervals. Reductions in red cell numbers and hemoglobin values occurred within a few days and became maximal at about 3 weeks. This was followed by a gradual return of the red cell and hemoglobin values to almost normal levels by approximately 60 days. Reticulocytosis and decreased red cell fragilities accompanied the anemia. Sedimentation rates increased slightly and total and differential white cell counts were unaffected by adrenalectomy. The various hemic alterations induced by adrenal removal could be prevented by administration of adrenal cortical extracts. To evaluate further the role of the adrenal in blood formation, adrenalectomized and control rats were subjected to the stress of lowered barometric pressures (311 mm Hg) for periods up to 21 days. Adrenal removal did not impair the ability of the rat to respond with increased red cell, hemoglobin and reticulocyte values to this stimulus. Bone marrow myelograms of the pressure-exposed adrenalectomized rats were no different from those of the controls.

Following a 3-week rest period, however, greater numbers of granulocytes and decreases in the numbers of nucleated erythroid cells with a resulting lowered erythroid-myeloid cell ratio became apparent in the marrows of the adrenalectomized rats. It is concluded that although adrenalectomy in the rat results in alterations in the red cell production and/or destructive mechanisms, the adrenal is not essential for the response to the erythropoietic stress imposed by lowered barometric pressures.

Pyrogen fever in rabbits effects of adrenalectomy and thyroidectomy RONALD GRANT, J DOROTHY HIRSCH AND BARBARA B HIRSCH (introduced by FRANK W WEYMOUTH) *Dept of Physiology, Stanford Univ, Calif*

Effects of prior adrenalectomy and thyroidectomy on changes in rectal temperature (RT), ear temperature (ET), respiratory rate (RR) and oxygen consumption (OC) following i.v. injection of pyrogens, have been determined. Normal fever includes two phases of rising RT associated with lowered ET and RR. An interpolated phase of stable or declining RT is associated with increased ET and RR. The first rise in RT is aided by a brief increase in OC not usually due to shivering. Adrenalectomy (accessories not removed, animals kept on DCA) had no marked effect on any of the changes listed, but shivering seemed to participate more in increasing OC. At room temperature (22°) thyroidectomized animals are hypothermic, the initial rise in RT is normal, but the secondary rise absent. Shivering is marked and stimulation of OC prolonged. ET and RR are low initially and show no marked changes. Thyroxine medication largely restores the normal responses. At 36° heat defense mechanisms are active, pyrogen causes normal changes in ET and RR and a weak biphasic fever. No shivering occurs. Most of the differences after thyroidectomy can be attributed to the low metabolic rate. It is concluded that neither adrenal nor thyroid secretions are essential intermediaries in fever but that absence of either gland causes increased participation of shivering. In thyroidectomized animals this is attributed to hypothermia. In adrenalectomized animals it may be due to removal of inhibition normally exerted by epinephrine.

Influence of carotid body removal upon the polycythemic response to discontinuous anoxia WILSON C GRANT *Dept of Physiology, Columbia Univ College of Physicians and Surgeons, New York City*

Carotid bodies were destroyed and/or aortic nerves sectioned with the right vagus in rabbits. Chemoreceptor removal was demonstrated by lack of NaCN response, marked depression of arterial O₂ saturation and pO₂, and absence of

hyperpnea when exposed to low O₂ mixtures. Loss of the carotid bodies was verified histologically. The carotid bodies were responsible for the great bulk of chemoreceptor activity in the unanesthetized rabbits since their removal alone abolished the NaCN response. The arterial O₂ saturation of an animal with unilateral carotid removal breathing low O₂ was halfway between that of the normal and bilaterally operated. No lasting hypertension was observed. Anoxia was produced in a chamber maintained at 400 mm Hg (16,500 ft) for approximately 6 hours/day, 6 days/week. The average cumulative exposure was 150 hours. The denervated animal was accompanied in the chamber by a 'dummy operated' control. Three animals with carotid body and aortic nerve removal, as well as 5 with only carotid body removal, showed polycythemia. The hematocrit value rose 39 to 72 %, O₂ capacity 23 to 36%, R B C 23 to 62 % above pre-anoxic control levels and the reticulocyte peak was 4 to 12 %. Control values were re-established in about 40 days after removal from chamber. Values in the normal animals varied from zero to 10 % above control levels with no appreciable reticulocytosis. Incomplete carotid removal usually resulted in intermediate blood changes. Because of the lack of hyperpnea, a severe anoxic anoxia was produced without the acapnia present in normal animals. Preliminary investigation of the influence of carotid body removal upon the erythropoiesis following hemorrhage or cobalt administration yielded results similar to those from normal animals.

Observations on *in vivo* inaction of testosterone propionate by liver of white rat JOHN T GRAY-HACK* AND W W SCOTT *James Buchanan Brady Urological Inst, Johns Hopkins Hospital, Baltimore, Md*

A study is being made of the effects of various manipulations such as starvation, dietary deficiency, carbon tetrachloride poisoning and hypophysectomy on the ability of the liver of the castrate adult male rat to inactivate testosterone propionate. The animals were castrate for a period of at least 3 weeks before 10 mg pellets of testosterone propionate were implanted subcutaneously and intrasplenically. They were then subjected to the manipulations outlined above to test the testosterone propionate inactivating power of the liver under these conditions. The size of the prostate was used as an indicator of androgenic activity in the general circulation. Our results thus far indicate that the mechanism by which the liver inactivates testosterone propionate persists even in the face of apparently severe damage to this organ, this is contrary to the effect of liver damage on inactivation of estrogen by the liver.

Simultaneous studies of heart and kidney functions in human subjects D M GREEN, A D JOHNSON*, W C BRIDGES*, J H LIHMANN* AND F GRAY* *Dept of Medicine, Univ of Washington School of Medicine, Seattle, Wash*

Combined cardiac and renal functional measurements were made on 61 patients. The functions measured included cardiac output, mean blood pressure, glomerular filtration rate, renal plasma flow and extracellular fluid volume. The subjects were so selected as to present an extensive range of values for the functions studied. Little correlation was demonstrated between cardiac output and the other functions measured. Wide differences in filtration rate, plasma flow and extracellular fluid volume were observed among patients whose outputs were approximately equal. Renal plasma flow was found related to glomerular filtration rate. Both functions were inversely related to systemic blood pressure. When the effect of renal plasma differences was held constant by the partial correlation technique, the relation of filtration rate to blood pressure became nonsignificant. Extracellular fluid volume did not correlate well with any of the other functions measured.

Constancy of responses to intra-arterial injections of mechohyl in isolated blood-perfused extremity source and influence of constrictor substances produced by blood donor animal HAROLD D GREEN, J MAXWELL LITTLE, LEWIS T FRANKLIN* AND HOWARD H WAYNE* *Dept of Physiology and Pharmacology, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem, N C*

The blood flow responses to intrafemoral artery injections of mechohyl in a dog's hindleg, perfused from its aorta varied with spontaneous fluctuations of vasomotor tone and perfusion pressure (*Federation Proc* 8: 50, 1949). To prevent changes of perfusion pressure a constant-pressure pump was inserted between the aorta and femoral artery. In this preparation flow decreased progressively from around 10 cc to around 2 cc/100 gm/min in about 3 hours indicating marked vasoconstriction which was humorally mediated, since it was prevented by neither nerve section nor complete amputation with perfusion by blood from a separate blood donor dog. Splanchnic section, adrenalectomy or nephrectomy in the blood donor dog had little effect, pithing or prolonged spinal ischemia by elevation of the C S F pressure caused a momentary further decrease in leg flow coincident with the rise in mean arterial pressure in the blood donor dog. Within about 30 minutes the blood donor's mean arterial pressure fell to around 40 mm Hg and simultaneously the leg flow rose to or above the initial rate where it remained for several hours. The initial rate of leg

flow also could be restored temporarily by substitution of a new blood donor. The percentile responses to injections of mechohyl varied inversely with the control leg flow throughout these procedures. Since none of the above changes could be accounted for by the recorded alterations in blood viscosity the progressive reduction in control flow and increase in response to mechohyl must be due to a constrictor agent produced by the blood donor dog under the control of its nervous system in response to some stress induced by the perfusion system.

Effect of oral cinchona alkaloids on circulation of dogs with experimental renal hypertension INEZ GREENE* AND E P HIATT *Physiology Dept, Univ of North Carolina School of Medicine, Chapel Hill*

We have found that oral doses of quinine or quinidine have very little effect on the blood pressure of dogs with renal hypertension, which is in marked contrast to the previously reported depressor effect of these alkaloids on dogs with experimental neurogenic hypertension. Five dogs were made hypertensive by the application of clamps to both renal arteries according to the method of Goldblatt. Oral doses (15 mg/kg) of one of the alkaloids were given to each dog several times a day for 3 days and the effect on its arterial blood pressure and renal hemodynamics was measured. Blood pressure was recorded optically from a needle inserted into a femoral artery. Glomerular filtration rate was estimated by the renal clearance of creatinine and effective renal plasma flow was determined by the clearance of p-aminohippurate. The concentration of the alkaloids in the plasma was measured at corresponding intervals. At plasma levels which in normal or neurogenic hypertensive dogs cause marked vasodilatation, the dogs with renal hypertension showed practically no such effect. These experiments are considered to be additional evidence that the site of the vasodilator action of these drugs in this concentration range is on the neuromuscular junction and not directly on the arteriolar smooth muscle. The maintenance of blood pressure in these dogs with alkaloid concentrations up to 8 mg/l also indicates that cardiac function is not markedly depressed.

Parathyroids and vitamin D in mineral stress ROY O GREEP AND CLARY J FISCHER* *Harvard School of Dental Medicine, Boston, Mass*

Intact and parathyroidectomized young rats received for 4 weeks purified diets which embraced a wide range in calcium phosphate ratios and absolute quantities. Each mineral combination was also fed with no vitamin D to each category of animal. In intact and operated animals the blood levels of calcium and phosphate showed a marked

tendency to reflect the relative concentration of these substances in the diet. Excursions in blood levels were, in general, more extreme after parathyroidectomy, indicating a definite but limited parathyroid capacity to maintain a mineral homeostasis. In parathyroidectomized rats fluctuations in blood phosphate produced by diet reciprocally altered blood calcium concentration in an opposite direction. Conversely, changes in blood calcium had little or no effect on phosphate. In intact rats the magnitude of the blood calcium and phosphate-raising effect of vitamin D was greatest in mineral deficiencies and least, or negligible, in their excess. Parathyroidectomized rats responded to vitamin D more uniformly, except that with high phosphate intakes the blood calcium was actually reduced due to excessive elevation of blood phosphate. Vitamin D is not essential for growth of intact rats given an adequate calcium phosphate intake and may impair growth in mineral imbalances, given to parathyroidectomized rats with normal mineral intake growth was greatly improved. The skeleton was weakened by every dietary mineral deficiency. High calcium diets produced calculi in the bladder and ureters; high phosphate diets caused severe nephrolithiasis. Observations on tetany and bone ash will be reported.

Respiration of cerebral cortex in vivo, in the absence of glucose R. G. GRENNELL AND P. W. DAVIES *Psychiatric Inst., Univ. of Maryland and Dept. of Biophysics, the Johns Hopkins Univ., Baltimore, Md.*

With the aid of the oxygen electrode, and a technique which permits perfusion of a localized area of cerebral cortex (through cannulation of a pial arteriole), *in vivo* measurements have been made of activity and rate of oxygen consumption of the cortex of the Suprasylvian gyrus of the cat, in the presence and absence of exogenous carbohydrate. The perfusion fluids used were modified, bicarbonate buffered Krebs solutions, equilibrated with 5% CO₂ at 38° C. Either Knox gelatine or crystalline serum albumin was added to maintain the normal colloid osmotic pressure, and these standard solutions with glucose have shown themselves capable of maintaining the normal pre-perfusion metabolic level over periods of as much as 2 hours, although they failed to do so when the gelatine or albumin were omitted. The animals were under sodium pentobarbital (Nembutal) anesthesia, and the temperature of the exposed area of the brain was carefully maintained at 38° C. The following observations have been made: 1) Up to 2 hours (the longest period during which perfusion has been carried out thus far) in the absence of carbohydrate, there has been no drop in the rate of the local cortical oxygen consump-

tion. 2) Lack of glucose has thus far shown no appreciable effect on the spontaneous electrical activity of the cells in the local area. 3) That the local oxygen consumption and activity can be altered has been demonstrated by perfusion with various concentrations of Nembutal, citrate, potassium, etc. Nembutal in 0.5 mM concentration drops the respiration to about 75-80% of normal, and at a concentration of 10 mM, the oxygen consumption has reached zero. The 0.5 mM concentration causes marked depression of the local electrocorticogram. These experiments would indicate that the brain cells, at least of a local area of the cortex, can use something other than carbohydrate as a substrate.

Interrelationship of cardiac output, blood pressure, and peripheral resistance during respiration ARTHUR L. GROPPER AND ARNOLD H. WILLIAMS (introduced by JOHN R. SMITH) *Hypertension Division, Dept. of Internal Medicine, Washington Univ. School of Medicine, St. Louis, Mo.*

It is well known that cardiac output and blood pressure vary during respiration. Starr and Friedland (*J. Clin. Investigation* 25:43, 1946) showed that ballistocardiographic complexes enlarge during inspiration and diminish with expiration. They found that the outputs of both the left and right hearts varied, the latter to a greater degree. Right heart output increased and left heart output decreased (e.g., systemic blood pressure dropped) during inspiration, and vice versa. As the size of the BCG complex reflects the sum of right and left heart outputs it is probable that the variations of output are greater than those which the size of the complexes would indicate. In the control periods of some recent experiments in normotensive patients (WILLIAMS, A. H. and H. A. SCHROEDER, *Proc. Am. Physiol. Soc.* Sept., 1949) BCG complexes showed phasic changes of 25% whilst variations of blood pressure were small. Even 10% changes of left heart output would have produced greater variations of blood pressure than those obtained if no compensatory adjustments had been made in peripheral resistance. Studies are in progress to demonstrate the reciprocal interrelationships of left heart output, blood pressure and regional peripheral resistance during respiration in normotensive and hypertensive subjects.

Study of protein fractions of gastric juice obtained by electrophoretic separation ALLAN L. GROSSBERG,* S. A. KOMAROV AND HARRY SHAY *Samuel S. Fels Research Inst., Temple Univ. School of Medicine, Philadelphia, Penna.*

Protein material of canine gastric juice secreted in response to sham feeding was analyzed electrophoretically. Juice was collected directly into

phosphate buffer pH 6.1, the final pH never fell below 6.0, thus precluding the possibility of auto-digestion. This material was dialyzed against water at 0°C until salt free and then lyophilized. Electrophoresis of solutions of this material was performed according to standard procedures (e.g. LOWESWORTH, L. G. *Chem. Rev.* 30: 323, 1952). Upon electrophoresis 1 peak representing the major part of the protein material were consistently observed. One or 2 additional less prominent peaks were also occasionally observed. Two electrophoretically well-defined fractions having electrophoretic mobilities, $\mu = -3.5 \times 10^{-5}$ cm²/volt/sec and $\mu = -7.9 \times 10^{-5}$ cm²/volt/sec in pH 6.08 phosphate buffer, $r/2 = 0.1$, were obtained, but probably neither represents a chemical entity. These fractions contain mucoproteins of different nature, as indicated by liberation of hexosamine and uronic acid after acid hydrolysis, in characteristically different proportions. The lowest ratio of hexosamine to uronic acid was obtained in the fastest moving protein and was lower than in any of the specimens of sham feeding juice analyzed without fractionation. The highest ratio approximated values obtained from spontaneously secreted alkaline gastric mucus. The fractions of intermediate mobility also had intermediate values for the relative concentration of hexosamine and uronic acid. All fractions upon acidification exhibited peptic activity. The data are interpreted as further evidence for the existence of more than one mucoprotein in gastric secretion, as reported previously (GROSSBERG, KOMAROV AND SHAY *Federation Proc.* 8: 62, 1949).

Intraarterial pressures before and after aortic resection for coarctation in man. ROBERT F. GROVER,* HENRY SWAN, II* AND CLARENCE A. MAASKE. *Depts. of Physiology and Pharmacology, and of Surgery, Univ. of Colorado Med. Center, Denver.*

Simultaneous recordings of the electrocardiogram and intraradial and intrafemoral arterial pressures were made by means of resistance type strain gauges in 7 patients with coarctation of the aorta. A comparative analysis of these records indicated that the femoral-to-radial pulse pressure ratio and the magnitude of the onset-to-peak interval of the femoral pulse wave were the most significant criteria for establishing the existence of a coarctation. These same criteria have now been employed to evaluate the effect of aortic resection on the hemodynamic status of these patients. The average femoral-to-radial pulse pressure ratio prior to surgery was 0.18. When again determined an average of 6 weeks post-operatively, the average ratio had been elevated to 0.69, a significant alteration toward the normal of 1.0. In every case, the onset-to-peak interval

of the femoral pulse was reduced to within normal limits. These changes imply a marked improvement in the vascular dynamics of these patients.

Increased sodium entry into squid giant axons during activity at high frequencies and during reversible inactivation of cholinesterase. HARRY GRUNDIIST AND DAVID NACHMANSOHN. *Dept. of Neurology, Columbia Univ. College of Physicians and Surgeons, New York City.*

Squid giant axons are able to carry 300 impulses/sec for several hours. Maximum carrying rate for times up to 6 minutes lies between 350 and 400 impulses/sec. Recent association of the spike with transient increased permeance of sodium suggests that the higher the rate and duration of nerve activity, the greater should be the entry of sodium into the axoplasm. In a preliminary series of experiments, individual giant axons were exposed to continuously flowing artificial seawater containing a moiety of Na²⁴ while stimulated at 100, 200 and 300/sec up to 30 minutes. Sodium entry was calculated from the radioactivity of the extruded axoplasm. Net entry because of 15 minutes activity (subtracting entry into resting nerve) doubled (5 mV/gm to 11 mV/gm) by increasing rate of activity from 100 to 300 impulses/sec. Under the same conditions 30 minutes activity produced net entry 6.4 and 14.6 mV/gm. Axons inactivated by DFP or eserine under reversible conditions showed still larger net sodium entry in 15 minutes, approximately 10 and 15 mV/gm. Present concepts of ion transport across cell membranes will be discussed in the light of these experiments, and include the possibility that cholinesterase is associated with 'sodium pump' mechanism, that its combination with acetylcholine or esterase inhibitors may alter the dynamic ionic equilibrium by inactivating this mechanism.

Dissolution of fibrin clots in the presence of concentrated purified thrombin. M. MASON GUEST AND ARNOLD G. WARE.* *Dept. of Physiology and Pharmacology, Wayne Univ. College of Medicine, Detroit, Mich.*

Fibrin clots prepared by the action of thrombin on 0.5% fibrinogen solutions are later completely dissolved by the thrombin at 37.5°C. The rate of solution is a linear function of the log of the thrombin concentration plotted against the log of time. Thrombin in a concentration of 9,000 units/ml produces clotting and dissolution of the clot 90 minutes later. Antifibrinolysin (antiplasmin) has no effect on the rate of breakdown of the clot while soybean antitrypsin has only a slight retarding effect when present in high concentration. The clot dissolving property of thrombin is destroyed by heat at a rate equal to the destruction of the clotting activity of the thrombin.

Relation of the biological activity of progesterone to the extent of its conversion to pregnanediol

H S GUTERMAN *Dept of Metabolic and Endocrine Research, Med Research Inst, Michael Reese Hospital, Chicago, Ill*

The excretion of urinary pregnanediol was studied following the administration of progesterone to women. The results indicate that the conversion of progesterone to pregnanediol is influenced by the physiological state and more specifically by the corpus luteum and/or the placenta. Pregnanediol amounts to less than 20% of the administered progesterone in the non-pregnant state in the absence of corpus luteum activity (5-19%) and in those pregnancies associated with apparent decreased progesterone secretion which end in abortion (7-19%). More than 25% of the progesterone is converted to pregnanediol when the corpus luteum is active in the non-pregnant state (25-44%) and when the corpus luteum and/or placenta is functional in normal pregnancy (28-44%) and pregnancy retained in spite of symptoms of threatened abortion and apparent decreased progesterone secretion (27-60%). From these observations it appears that the conversion of progesterone to pregnanediol is increased in the presence of the functioning corpus luteum or placenta. The enhanced conversion pattern in pregnancies which are retained suggests that a metabolic factor is introduced by these endocrine structures which may have significance in maintaining the integrity of gestation.

Evidence for adrenergic sweating in man

HENRY HAIMOVICI (introduced by H B VAN DYKE)
Surgical Div, Montefiore Hospital, New York City

Dibenzamine, an adrenergic-blocking agent, was found to inhibit spontaneous sweating in man. This observation raised the problem of the presence of an adrenergic component in the nervous mechanism of sweating in man (HAIMOVICI *Proc Soc Exper Biol & Med* 68 40, 1948). In the present investigation, the anhidrotic effect of Dibenzamine was demonstrated by a colorimetric method in 31 subjects and by the electrical skin resistance in 12 subjects. The sudomotor response to adrenergic drugs was studied by intradermal injections. Epinephrine (0.1 γ to 0.3 γ) induced sweating in 84.0% of the subjects. Its sudomotor effect was consistently inhibited by Dibenzamine. Norepinephrine (0.1 γ to 0.3 γ) induced sweating in 74.0% of the subjects, while Isuprel (0.1 γ to 0.3 γ) provoked no response in 60.8% and delayed positive response in 32.1% of the subjects. The results obtained with norepinephrine and Isuprel suggest that sympathin E and the excitatory component of epinephrine are responsible for the sudomotor ability of the adrenergic systems. Intradermal

injections of epinephrine and acetylcholine or Mecholyl into the same point indicate that the secretory activity of the sweat glands is augmented both by cholinergic and adrenergic stimulation. These agents exert therefore a synergistic sudomotor action. Since sweating in man can be elicited by adrenergic agents and inhibited by an adrenergic-blocking agent, it is concluded that, in addition to the known cholinergic fibers supplying the sweat glands, there is also an adrenergic component in the nervous mechanism of sweating in man.

Absolute numbers of circulating eosinophil blood cells in dogs starved for three days

F HALBERG,* J R R BOBB AND M B VISSCHER
Dept of Physiology, Univ of Minnesota, Minneapolis

Thirty-five unselected dogs, previously dewormed, under standard housing conditions were used simultaneously in this study. The week preceding each experiment they were maintained on a diet consisting of $\frac{1}{2}$ pound meat, multivitamins, biscuits and water *ad libitum*. Eosinophils were determined in the counting chamber in blood withdrawn from the jugular vein, on the first day 4 samples from each dog at exactly 4-hour intervals (6 A.M. till 7 P.M.) and 2 daily on the following two days (6 to 7 A.M. and 6 to 7 P.M.). The data collected during the 60-hr fast—as well as those obtained from a second experiment carried out 2 weeks later on the same dogs, starved for 84 hours—did not support the concept of a regular or considerable eosinopenia (exceeding a -30% change) in the dogs starving for 60 hours or less (the only dog which showed a fall of 85% at the count after 60 hours of fasting died the same day from an infection). However, the results obtained after 84 hours of fasting averaged -51% of the starting value which under the conditions of our experiment may be considered as the time of manifestation of starvation eosinopenia in the dogs investigated.

Inactivation of gonadotrophins by liver and liver homogenates

B VINCENT HALL (introduced by AUSTIN M BRUES) *Univ of Illinois, Urbana, and Biological Division, Argonne National Lab, Chicago, Ill*

It is well known that gonadotrophic hormones rapidly disappear or lose their effectiveness after release or injection into an animal. To investigate the possible role of liver in the inactivation of gonadotrophins, implants of anterior lobes of rat pituitaries were made on 4 consecutive days either directly beneath the capsule of the spleen, into the abdominal cavity or subcutaneously in 72 immature female rats. The ovaries of the animals with subcutaneous implants were distinctly larger at 5 days than those receiving intrasplenic or

intraperitoneal implants. The ovaries of animals receiving intrasplenic implants were least developed. Incubation of chorionic gonadotrophins for 1 hour at 37°C with fresh rat liver homogenates resulted in a significant reduction in hormonal activity as tested by increase in size of ovaries and uteri of immature rats. Incubation for 1 hour with heat inactivated liver homogenates, or with saline solutions alone, will effect some inactivation of the chorionic gonadotrophins, but not to the extent resulting from incubation with fresh liver homogenates. The results suggest that the rapid disappearance of gonadotrophins in the organism may be largely due to inactivation in the liver.

Pattern of gas expulsion from human lungs during rapid decompression F G HALL, *Dept of Physiology and Pharmacology, Duke Univ School of Medicine, Durham, N C*

The pattern of gas expulsion from the lungs of each of 6 medical students subjected to rapid decompression from 225 mm Hg pressure to 565 mm Hg in an altitude chamber was recorded by an optical manometer. From the rheopneumograms thus obtained the velocities and volumes of gases expelled were determined for various rates of decompression. Results of these determinations are compared with the residual and reserve air determinations for the same individuals.

Mechanism of magnesium hypothermia in the rabbit V E HALL AND F A ELLIS * *Dept of Physiology, Stanford Univ School of Medicine, Stanford, Calif*

A dose of 25 mm/kg of magnesium chloride given intraperitoneally to unanesthetized rabbits at an environmental temperature of 28°C caused a body temperature fall of 0.32°C. Since the O₂ consumption was not significantly altered, the reduction in body temperature was attributable not to a reduction in heat production, but to increased heat loss by means of the polypnea and cutaneous vasodilatation, which have been found under these conditions by Heagy and Burton and by ourselves. The same dose given at an environmental temperature of 0°C caused a body temperature fall of 1.62°C. The O₂ consumption, which before injection was approximately double that at 28°C, was reduced following MgCl₂ administration by 29.9% (average of 10 experiments). Since we have shown that in cold environments MgCl₂ does not cause either polypnea or cutaneous vasodilatation, the fall in body temperature under these conditions appears to be due largely to a reduction in heat production, attributable to an interference with the nervous mechanism of defense against cold. The significance of these findings relative to the effect of magnesium salts on temperature regulation will be discussed.

Complete individuality of canine blood as the source of an urticaria-producing factor ANGIE S HAMILTON AND BERT MORROW (introduced by J E RHOADS) *Harrison Dept of Surgical Research, Univ of Pennsylvania Schools of Medicine, Philadelphia*

In the absence of erythrocyte incompatibility (HAMILTON *Am J Physiol* 151: 525, 1948) and/or non-specific factors (e.g. particulate matter or coagulant factors), the reaction to the individuality factor (IF) (FREEMAN, N E, AND A E SCHICKEN *Science* 96: 39, 1911) contained in heparinized or citrated plasma and serum is manifested by urticaria in infused recipients and by stinging of a bleb following intradermal injection in the presence of circulating dye (T-1824). Auto-serum fails to produce these phenomena in normal or hypersensitive dogs. A skin assay test for qualitative and semi-quantitative determination of the amount of IF contained in heparinized plasma or serum has been perfected. The test requires circulating dye, otherwise only hypersensitive dogs or so-called 'allergic' humans show qualitative differences in response to auto- and iso sera. Methods of handling blood affect the responses to iso sera. The content of IF is minimized by immediate separation of plasma from cellular elements at 4°C. It is increased by short contact with cellular elements *in vitro* at 37°C. Heparinized plasma gives stronger reactions than citrated plasma. Pooling is ineffectual. The IF is thermolabile, being significantly decreased by heating at 62°C for 30 minutes. Stress conditions in recipients and in donors have been studied. Recipient response to iso-sera is decreased by anesthesia and by severe illnesses. Moderate to severe blood loss immediately preceding blood sampling markedly decreased the responses of other dogs to the serum of the bled donor.

Relation between the size of the heart and the stroke index W F HAMILTON *Dept of Physiology, Univ of Georgia School of Medicine, Augusta*

In a series of dogs the heart size was calculated from the x-ray shadow and the stroke index was derived from the pulse contour. These two variables were compared during hemorrhage, epinephrine infusion, and during the action of acetylcholine, histamine, and other drugs. Balloons on catheters were passed down the vena cava to various sites and inflated. This procedure cut off various fractions of the venous return and tended to diminish the heart size and stroke volume. Increase in aortic pressure tends to decrease stroke volume and to increase heart size whereas increase in venous pressure and diastolic time tend to increase both stroke volume and heart size. Data are being accumulated with it in mind to work out interrelationships among these factors.

Comparative toxicity of chloral hydrate and chloral alcoholate PHILLIP V HAMMOND,* DONALD E STULKEN* AND WILLIAM A HESTAND *Lab of Animal Physiology, Dept of Biological Sciences, Purdue Univ, Lafayette, Ind*

According to popular belief the mixing of chloral hydrate with an alcoholic beverage results in the formation of chloral alcoholate, a product supposedly having greater hypnotic properties than the hydrate, the mixture being known as a 'Mickey Finn'. A comparative study of the toxicities of the two compounds was undertaken by determining their LD_{50} . Wistar rats and mice of the Hygienic and Swiss strains were used, the former being injected intraperitoneally, the latter subcutaneously with varying amounts of 4% solutions. In all experiments a total of 161 mice and 123 rats was used. LD_{50} was calculated by Wright's method. All surviving animals were discarded. In terms of gm/kg dosage in both species the toxicity of chloral hydrate proved greater than that of the alcoholate. The LD_{50} of chloral hydrate intraperitoneally in rats was 0.628 gm/kg, of chloral alcoholate 0.756 gm/kg. The LD_{50} of chloral hydrate subcutaneously in mice was 0.909 gm/kg, of chloral alcoholate 0.945 gm/kg. These results agree in principle with those of Adams who used intragastric administration (ADAMS, W L J *Pharmacol* 78:340, 1943).

Reaction to pain as determined by galvanic skin response JAMES D HARDY AND MANUEL FURER* *Depts of Physiology and Medicine, Cornell Univ Med College, New York City*

A study of the galvanic skin response as a reaction to graded standard pain intensities was carried out on 4 normal subjects. Pains were induced by intense thermal radiation and graded from threshold to 8 dols, in steps of 2 dols. The galvanic skin response was measured with chloridized silver electrodes attached to the palmar surface of the index and middle fingers. Three series of experiments were performed. 1) The subjects, in a relaxed state, were exposed daily over a 6-month period to pains presented in a fixed order of 0, threshold, 2, 4, 6 and 8 dols. The galvanic skin response to each pain was recorded. 2) The subjects were similarly studied in hot and cold environments. 3) Studies were made during and after events calculated to induce anxiety. The following observations were made. 1) In contrast to the uniform accuracy with which the pains were perceived, there were marked variations in the reaction to the pains. 2) In the first series of experiments the pains on daily repetition gradually lost their effectiveness in evoking a reaction. Several weeks were required for complete adaptation of the response and the time required for adaptation was different for each subject. 3) The magnitude of the galvanic skin response increased

in proportion to the intensity of the experimental pains. 4) In the second series of studies exposure of the subjects to very hot (50°C) or very cold (7°C) environments reduced or suppressed the galvanic skin response. 5) In the third series of experiments situations designed to increase the subjects' anxiety increased the galvanic skin response to the pains for a few days, but adaptation to the new situations was rapid. 6) The subjects could not predict the degree of their responsiveness to the pains or correlate it with estimates of their emotional states.

Phases of ectopic ventricular activity following experimental coronary occlusion A SIDNEY HARRIS *Dept of Physiology, Baylor Univ College of Medicine, Houston, Texas*

Ligation of the anterior descending coronary artery of the dog produces ventricular ectopic activity in phases related to time elapsed since occlusion. The first phase begins about 2 minutes and ends about 10 minutes after occlusion. This is a period of increasing frequency of idioventricular complexes and danger of early ventricular fibrillation. This phase can be eliminated by two-stage occlusion. The second phase follows and lasts about 4½ to 8 hours. It is characterized by absence or low frequency (0-5 per minute) of ectopic beats, with exceptions related to the anesthetic. Following ligation under pentothal sodium, ectopic frequencies up to 50 per minute have appeared 2½ to 4½ hours after occlusion. Following pentobarbital sodium significant ectopic frequencies have appeared 3½ to 4½ hours after occlusion. Following ether no animal out of 4 operated has exhibited increased ectopic frequencies earlier than 4 hours after occlusion and only one earlier than 4½ hours. Following morphine-barbital sodium occlusions and following pentobarbital sodium occlusions combined with upper thoracic sympathectomy no increased ectopic activity has occurred during the first 4½ hours. Second phase ectopic impulses are suppressed by barbiturate administered after they develop. The third phase develops most intense ectopic ventricular activity. Following its onset 4½ to 8 hours after occlusion the ectopic frequency increases rapidly to high levels. This activity follows occlusions under all anesthetics and after upper thoracic sympathectomy. It can develop soon after the administration of barbiturate, and persists if barbiturate is given after they develop.

Suppression of ventricular ectopic impulses accompanying acute myocardial infarction by diphenylhydantoin sodium and barbiturates A SIDNEY HARRIS AND ROBERT H KOKERNOT* *Dept of Physiology, Baylor Univ College of Medicine, Houston, Texas*

Experimental occlusion of the anterior descending artery of the dog's heart produces ectopic

ventricular tachycardia after a latency of $1\frac{1}{2}$ to 8 hours. This coincides with the duration of ischemia required to produce histological signs of necrosis. There is evidence that ectopic impulses originate in the boundary of the infarct. It is probable that some product of necrosis acting within the hyperexcitable boundary causes the discharges. In focal epilepsy the seizures are initiated by nerve cell discharges arising in the boundary of the brain lesion, and excised epileptogenic tissues are found to contain areas of acute necrosis. Because of these apparent similarities, drugs that prevent focal seizures are being tried as possible suppressors of ventricular ectopic rhythms. Diphenylhydantoin sodium (dilantin) given to unanesthetized dogs with ectopic ventricular tachycardia at its maximal intensity causes cessation of ectopic beats for a variable period and greatly diminishes ectopic frequency many hours if 200 mg/kg is given in divided doses within 3 or 4 hours. Later, with less intense ectopic drive smaller amounts suffice. In some animals effective doses of dilantin during the intense stage produce involuntary muscular movements, but not in all. Phenobarbital sodium, up to 60 mg/kg, fails to control ectopic activity when intense, but potentiates dilantin. After phenobarbital sodium, dilantin, 10 to 25 mg/kg, has produced lasting restoration of normal rhythm. Pentobarbital sodium potentiates dilantin also. Barbiturates increase the toxicity of dilantin, but the potentiation of ectopic impulse suppression offsets the increased toxicity.

Hypothalamic control of the secretion of adrenocorticotrophic hormone GEOFFREY W. HARRIS AND J. DE GROOT (introduced by ROBERT S. MORISON) *Physiological Lab, Cambridge, England*

In previous work (with the collaboration of Dr H. F. Colfer) it has been shown that emotional stress in rabbits is followed by a marked drop in the absolute number of blood lymphocytes, and that this response is abolished by hypophysectomy. In order to investigate the pathway between the brain and adeno-hypophysis which underlies this lymphopenic response, different regions of the hypothalamus and hypophysis have been electrically stimulated by the remote control method in unanesthetized, unrestrained rabbits. It was found that stimulation of the posterior region of the tuber cinereum or mammillary body resulted in a lymphopenia which was similar in time relations and magnitude to that following an emotional stress stimulus. Stimulation of other regions of the hypothalamus or hypophysis did not elicit the response. The lymphopenic response which followed an emotional stress stimulus in normal rabbits was abolished by lesions in the zona tuberalis (2 cases), and, in most cases, abolished or

diminished by transverse lesions in the posterior region of the tuber cinereum or in the mammillary body. Similar lesions in the posterior part of the pars distalis, pars intermedia, or lesions which interrupt the infundibular stem, were compatible with normal responses. The conclusion is drawn that anterior pituitary secretion of the adrenocorticotrophic hormone is under neural control via the hypothalamus and the hypophysial portal vessels.

Secretion of fat factor of the adrenal FRANK A. HARTMAN AND T. Y. LIU * *Ohio State Univ., Columbus*

Blood from the left adrenal of heparinized nembutalized dogs was assayed for the fat factor. Blood removed was replaced by blood from a second dog. The hormone was extracted from the plasma by means of ethylene chloride. It was assayed on adrenalectomized starved mice. Six of 14 dogs secreted very little fat factor. In the dogs that were secreting appreciable amounts of the hormone there was no change produced during 4-6 hours of the experiment. Injections of ACTH which produced marked increase in gluconeogenic hormone were ineffective on fat factor secretion.

Inability of desoxycorticosterone acetate to prevent the sodium excretion produced by mannitol diuresis R. B. HARVEY,* D. H. SIMMONS,* T. HOSHINO* AND M. B. VISSCHER *Dept of Physiology, Univ of Minnesota, Minneapolis*

Recent work of Pitts and others suggests that humoral mechanisms may play a role in the increased rate of sodium excretion occurring during mannitol diuresis. In our laboratory unanesthetized dogs were subjected to osmotic diuresis with 1.32 molar mannitol given intravenously at the rate of 0.2 cc/lb/min after having been on salt-poor (rice) diets for one to two weeks. Under similar conditions, but with administration of 1 mg/lb/day of desoxycorticosterone acetate (DCA) in sesame oil subcutaneously for 6 to 8 days previously, the experiments were repeated on the same animals. Determinations were made of urine and serum sodium concentrations, rate of urine flow, urine and serum total osmotic pressures (Hill-Baldes vapor tension method), and creatinine clearances before and after the injection of mannitol. It was found that the injection of mannitol increased the rate of sodium excretion, either in terms of moles/lb/min or as tubular rejection fraction of sodium, 50 to 300 times over control values. It was also observed that urine flow was increased up to 50% of glomerular filtration rate. The plasma sodium level fell an average of 17 mmol/liter yet the serum total osmotic pressure rose by an amount equivalent to as much as 30 mEq of sodium chloride per liter. None of the variables measured was significantly altered after the administration of DCA.

Radiophosphorus in mosquitoes C C HASSETT
(introduced by W H CHAMBERS) *Medical Div, Army Chemical Center, Md*

Data are presented showing paths of absorption of P^{32} and its distribution in the tissues of *Aedes aegypti*, as studied by radioautographs and by Geiger-tube counting technique

Mechanism of fibrous pepsin-albumin digestion
TERU HAYASHI AND GEORGE A EDISON *Dept of Zoology, Columbia Univ, New York City*

A mixture of pepsin and albumin buffered at pH 4.4 (mixture pH) when placed dropwise on the air-water interface of a Langmuir trough buffered at pH 4.0 (trough pH) forms a monomolecular film at several dynes pressure. Compression of the film forms a fiber which, when immersed in HCl at pH 1.5, undergoes autodigestion. No autodigestion occurs if the pepsin and albumin are placed separately on the same air-water interface. They must be in mixture prior to the formation of the film, showing that 1) the autodigestion is due to the fibrous pepsin rather than contaminating native pepsin and 2) that an interaction between pepsin and albumin occurs at the mixture pH of 4.4, this interaction being a necessary part of the enzymatic action of pepsin. Mixture pH's of 5.0, 6.0 and 6.6 are found to be progressively less effective in promoting autodigestion. A mixture pH of 7.2 shows no autodigestion. The interaction between pepsin and albumin may be shown by titration with saturated ammonium sulfate. The precipitate thus formed is measured photometrically by the amount of non-scattered light at 420 m μ passing through the suspension. The results show that at mixture pH's of 4.4, 5.0, 6.0, a complex of pepsin and albumin is formed, but that at pH 7.2, no complex formation occurs. It is concluded that 1) the autodigestible albumin-pepsin fiber is a stabilized enzyme-substrate complex and 2) the formation of enzyme-substrate complex is dependent on the establishment of linkages, probably salt linkages, between the pepsin and albumin.

Comparison of hemodynamics in pulmonary and systemic circulations in various diseases
FLORENCE W HAYNES AND LEWIS DEXTER*
Med Clinic, Peter Bent Brigham Hospital, and Dept of Medicine, Harvard Med School, Boston, Mass

By means of venous catheterization, pressures in the right auricle, right ventricle, pulmonary artery (PA), pulmonary 'capillaries' ('PC') and brachial artery have been recorded, as previously described, in normals and in patients with pulmonary hypertension (HT). A graph of progressive pressure changes through the lesser circulation compared with those accepted for the

systemic circulation emphasizes the following points. In normals the gradient between mean PA and 'PC' pressures is 4-10 mm Hg and the 'PC' pressure approximates the PA diastolic pressure. In contrast, the arterial-capillary gradient in the systemic circulation is many times that in the lung. In patients with pulmonary HT and normal 'PC' pressure, as in pulmonary vascular disease, the PA-'PC' gradient may reach 40 mm Hg and the PA diastolic pressure is usually well above the 'PC' pressure. This HT in the pulmonary circuit is in some respects analogous to arterial HT in the systemic circuit. In Eisenmenger's complex the gradient may equal that on the systemic side. In patients with elevated 'PC' pressure, as in mitral stenosis and left ventricular failure, the mean PA pressure is elevated either with a normal PA-'PC' gradient or, if the 'PC' pressure is excessive, with a widened gradient. This association of PA and 'PC' pressure elevations has no analogy of comparable degree in the systemic circulation. Since in none of the cases discussed has the pulmonary blood flow been increased above normal, an increased PA-'PC' gradient represents increased resistance. In systemic HT without cardiac failure, normal PA and 'PC' pressures exist.

Characterization of corticosteroids released from perfused cow adrenals OSCAR HECHTER *Worcester Foundation for Experimental Biology, Shrewsbury, Mass*

Previously, it was shown that perfused bovine adrenals respond to the addition of ACTH by a marked increase in the release and biosynthesis of corticosteroids (HECHTER, *Federation Proc* 8:70, 1949). In this study, the corticosteroids secreted by perfused preparations, in the absence and presence of ACTH, have been fractionated in a manner designed to estimate the number and character of the corticosteroids released. Adrenal perfusate extracts (HECHTER *et al*, *Arch Biochem*, in press) were fractionated by chromatography on silica gel. Under standardized conditions, the polarity of solvents requisite to elute reference steroids was determined by following the formaldehydrogenic steroid (FS) content of successive eluates. Desoxycorticosterone was removed from columns by benzene-ether mixtures (1:1-1:2), but not by benzene, whereas corticosterone was eluted by ether-ethyl acetate mixtures (1:1), but insignificantly by ether. In adrenal perfusates, wherein ACTH was not employed, two peaks of FS were observed in the benzene-ether eluate range. From color tests, it appears that one of these peaks may represent desoxycorticosterone. There is no or only a slight peak of FS in the ethyl acetate eluate range in such perfusates. In

preparations where ACTH was employed, in addition to the peaks previously described there was, in 2 or 3 experiments, the appearance of a new high peak of FS in the fractions eluted by ethyl acetate ether mixtures. This material released by ACTH has in one case been crystallized and appears to be 17-(α)-hydroxycorticosterone, as evaluated by mixed melting points and appropriate color tests.

Studies on biological and photochemical action of ultraviolet radiation at low temperatures F HEINMETS AND W W TAYLOR (introduced by ORR E REYNOLDS) *Depts of Biophysics and Bacteriology, Naval Med Field Research Lab, Camp Lejeune, N C*

There is a large number of studies concerning the fundamental mechanism of the action of the ultraviolet radiation on biological materials and chemical substances. For the liquid medium, it is difficult to differentiate between the primary and the secondary processes during the irradiation. This paper deals with studies of ultraviolet radiation on *B. action Coli* bacteria in the frozen state. The rate of inactivation depending on various experimental parameters has been determined. The photo reactivation of bacteria, which had been subjected to ultraviolet irradiation at low temperature, has also been studied. Various factors, such as temperatures, storing time after irradiation, etc. influencing the photo reactivation rate, have been investigated. At the same time, the photo-chemical decomposition of the tyrosine and alcohol soluble protein Zein has been investigated. As a decomposition measure, the changes of the absorption characteristics of the solution under study, have been used. There is evidence, that in the frozen state, the secondary chemical reactions are inhibited. This is revealed in the changes in the absorption characteristics of protein or amino acid solution, when compared with the experiments in the liquid phase. An attempt will be made to compare the photo-decomposition data with the biological inactivation results.

Vacuum Spark discharge with liquid-jet electrode as a radiation energy source for photochemical reactions and biological inactivations F HEINMETS AND W W TAYLOR (introduced by ORR E REYNOLDS) *Depts of Biophysics and Bacteriology, Naval Med Field Research Lab, Camp Lejeune, N C*

The Vacuum Spark has been used in the field of spectroscopy as a source of high energy photons. An experimental arrangement for studies of photochemical reactions and biological inactivations, by the vacuum spark discharge with one liquid-jet electrode, is described and the general instrumental set-up presented. The decomposition of

tyrosine solution is used to demonstrate the photochemical action of the vacuum spark discharge. The influence of various experimental factors, such as gas pressure, electrode potential, velocity of jet flow, etc. on the rate of tyrosine decomposition has been studied, and experimental data will be presented. The action of the vacuum discharge spark on various bacteria has been studied, and in certain experimental conditions, complete inactivation of the bacteria was obtained. Further, the influence of various experimental parameters on the inactivation rate of bacteria will be discussed. Experimental results of the bacterial inactivation and the photochemical decomposition of tyrosine will be compared and analyzed. Furthermore, the vacuum spark discharge and ultraviolet irradiation action on tyrosine solution have been studied on a comparative basis, and the resulting changes in the ultraviolet absorption characteristic analyzed for both cases.

A quantitative method for measuring pulmonary edema in the extirpated lungs of guinea pigs ALLAN HEMINGWAY *Dept of Physiology, Univ of Minnesota, Minneapolis*

The present methods now used in determining pulmonary edema usually consists of a gross examination of the extirpated lung and a visual inspection to determine qualitatively the presence of congested areas, petechia, fluid in the bronchi, the texture of the lung and its general color. The sole quantitative determination has consisted of a measurement of the lung weight. In order to obtain more quantitative information on determining the degree of pulmonary edema investigations have been made on chemical analytical methods for determination of those changes which have occurred as a result of the edema. A method has been devised whereby guinea pig lung is divided into four fractions: 1) insoluble protein nitrogen, the nitrogen remaining in the insoluble residue after grinding with sand and extracting with one per cent NaCl solution, 2) the pulmonary hemoglobin, determined spectrophotometrically from an aliquot of the saline extract but using a special extraction procedure for elimination of turbidity due to lipids, 3) the soluble protein fraction consisting of soluble protein nitrogen, other than hemoglobin nitrogen, in the saline extract, and 4) non-protein nitrogen of the saline extract determined by soluble nitrogen remaining after protein precipitation with tungstic acid. In addition a method has been devised for measuring density and volume of the extirpated lung. Normal values with their biological variations have been established on a series of guinea pigs.

Factors influencing venous pressure in foot of erect human during quiescence J P HEARY,

O H GAUER* AND E E MARTIN * *Aero Med Lab, Air Materiel Command, Wright-Patterson Air Force Base, Dayton, Ohio*

Three subjects were submitted to 6 series of tilt table experiments in an air-conditioned room adjusted to induce vasomotor responses ranging from sweating to shivering states. The rate of increase of venous pressure in the foot after tilting from the horizontal to upright posture depended upon the degree of vasodilation. When hot the pressure attained 80% of the full potential value of approximately 100 mm Hg in less than 20 seconds, when comfortable, this required 90 seconds and, when cool, 3 minutes after tilting the pressure was still less than 50% of the full value. Tests during quiet standing showed that normal postural activity reduced the mean venous pressure when cool and when comfortable to approximately 55 and 65 mm Hg, respectively. When sweating, these movements were insufficient to sustain a low pressure and the mean level became 90 mm Hg. This pressure exceeds by 30 mm Hg any probable counter-balancing combination of osmotic and tissue pressures. The rhythmic inflation of counter-pressure clothing (anti-g suits) can be substituted for the massaging effect of the muscles on the vessels. Thus during standing-walking, when hot, the mean pressure in 9 subjects was 67% and when cool, 41% of the resting value. When seated and using the suit, the corresponding values were 72% and 47%. It is suggested that such clothing might be employed to aid circulation in the lower extremities in certain clinical conditions.

Maximal oxygen intake and renal plasma flow in patients with aortic insufficiency AUSTIN HENSCHEL, THOMAS B GIBBONS* AND CARLETON B CHAPMAN * *Lab of Physiological Hygiene, Univ of Minnesota, Minneapolis*

The maximal oxygen intake and renal plasma flow were measured in 8 normal young men and 7 male patients of similar age, physique and exercise habits, who had mild to moderate aortic insufficiency due to rheumatic fever. Renal plasma flow was measured using a constant injection of para-aminohippurate at rest, during two 16-minute periods of walking at 3 miles per hour on a 10% grade, and at supine rest for 40 minutes following the work. Maximal oxygen intake was determined from 1 minute 45 seconds to 2 minutes 45 seconds of a 3-minute run at 6 miles per hour on a grade adjusted to the performance capacity of each subject. The maximal oxygen intake was 44.03 cc/kg/min and 37.43 cc/kg/min for the normal and cardiac subjects, respectively. The 15% difference in maximal oxygen intake for the 2 groups of subjects is statistically highly significant. The mean resting renal plasma flow cor-

rected to 1.73 sq meters of body surface was 495 and 576 cc/min in the patients and normal subjects, respectively, the difference is statistically significant. During exercise the renal plasma flow was decreased by 25% of the resting value for each group. Forty minutes after the cessation of the exercise the renal plasma flow had returned to the pre-exercise resting level in most of the normal and cardiac subjects.

Dielectric properties of tissues important in microwave diathermy J F HERRICK, D G JELATIS* AND G M LEE * *Mayo Foundation, Rochester, Minn*

Microwave diathermy has become an integral part of medical diathermy since it was approved by the Council of Physical Medicine and Rehabilitation of the American Medical Association. This relatively new type of diathermy has proven to be an efficient method for heating certain localized areas of the body. The ultimate objective in studying the dielectric properties of animal tissues was to understand the heating of these tissues by microwaves. We wished to explain, if possible, the experimentally observed temperature distribution produced in the tissues by microwaves. The amount of heat developed in biological tissues by microwave diathermy is dependent on the dielectric properties of the tissues. Since these properties vary with frequency, it is desirable to measure them at the actual frequencies used for microwave diathermy. Observed values are presented for the dielectric constant and loss of freshly excised samples of such tissues as liver, muscle, fat, bone and bone marrow. The dielectric properties of certain body fluids will also be presented. The design of a 'transformer' for increasing the transfer of microwave power into a particular tissue such as muscle is given as an example of the utility of the dielectric data. The equipment used for measuring dielectric constant and loss was the microwave dielectrometer which was designed and constructed by one of us.

Simultaneous partitional calorimetry and estimation of blood flows in main skin regions of the body ALRICK B HERTZMAN AND WALTER C RANDALL *Dept of Physiology, St Louis Univ School of Medicine, St Louis, Mo*

Cutaneous evaporative, radiative and convective heat losses and blood flows were estimated repeatedly and approximately simultaneously in the forehead, cheek, chest, abdomen, arm, forearm, thigh, calf, hand and foot of nude subjects in the operative temperature range of 27-37°C over an observational period of 4 hours. Although each region exhibited variations in the rate of heat loss during an observational period, comparison of the mean values for the total 4-hour heat loss from each region indicates a tendency towards

constancy in each area with the exception of the forehead (heat loss rises) and arm (heat loss falls) as the operative temperature rises. Scatter in the individual data appear with the onset of sweating, increases with the rise in temperature and correlates with the sudomotor patterns of individual subjects. The simultaneous estimations of the cutaneous blood flows from the skin pulses and also from the thermal data generally agree with respect to the onset and development of the cutaneous dilatations in all areas. Skin pulse estimates of blood flow (calculated from the flow equivalent of the finger pad pulse) were usually about 40% higher than the thermal estimates in all areas other than the forehead and dorsum of the hand and foot. The three latter areas exhibited large discrepancies in flow estimates. Both criteria agree on the existence of high flows in head skin, palm and sole of foot as may be predicted from vessel counts.

Energy cost of flying multi-engined aircraft FRED A HITCHCOCK *Med Research Lab, Civil Aeronautics Admin, Aeronautical Center, Oklahoma City, Okla*

As the first phase of an investigation of the factors involved in pilot fatigue, the respiratory metabolism and energy output of pilots while flying multi-engined aircraft (DC-4) has been measured. The subjects were all experienced pilots who were enrolled in refresher courses at the Aeronautical Center. The procedure followed was as follows. The subject rested for 20 minutes on a bunk located just to the rear of the pilot's compartment. Then expired air was collected for 10 minutes by means of an A-14 mask and Douglas Bag. During this part of the experiment the plane was in the air with another student pilot at the controls. After being in the air for about one hour this student landed the ship and the pilot who was serving as subject for the day took over the controls. After he had had the ship in the air for about 10 minutes expired air was collected for a second period of 10 minutes while he executed various maneuvers with the aircraft. The volume of expired air was measured with a calibrated dry test meter. Samples were collected over mercury and analyzed by means of the Haldane Air Analysis apparatus. The ventilation volume, O_2 consumption, CO_2 production, total calories and calories per sq m of body surface were then calculated, a) while the subject was resting and b) while he was flying the aircraft. The average for 10 such tests show that the caloric output while flying the plane is about twice that while resting.

Facilitating effect of local strychninization on pressor responses evoked from cerebral cortex E C HOFF, H G LANGFORD,* J W VESTER,* W W BECKNER* AND P R THOMAS * *Neuro-*

logical Science Lab of Med College of Virginia, Richmond

Hoff and Green (*Am J Physiol* 117 411, 1936) reported that stimulation of certain areas of the frontal lobe results in transient elevations of blood pressure. From the cat's cortex posterior to this pressor area as far back as the sylvian fissure, blood pressure falls have been elicited. These alterations in pressure are regularly reproducible and under standardized conditions exhibit constant latency, amplitude, and duration. In the present experiments, the influence of local strychninization upon the excitability of the pressor areas has been examined in cats. In control animals, weak faradic stimulation of symmetrical foci on the left or right anterior sigmoid gyrus evoked rises of blood pressure of 20-40 mm Hg, enduring 15-20 seconds. Four to 6 minutes after local application of 3% aqueous solution of strychnine sulfate to the excitable focus on the left or right anterior sigmoid gyrus, stimulation of the strychninized focus or the symmetrical contralateral focus gave greatly enhanced pressor responses. These blood pressure rises after local strychninization were of the order of 80-150 mm Hg above the baseline, the arterial tension subsiding in 4-20 minutes. This facilitation of blood pressure responses from the pressor area of the feline cortex is derived from the localized action of strychnine at the application site, or may be due to more generalized effects upon the excitability of the CNS as a result of absorption into the blood stream. Experiments are in progress to determine this point.

Effect of oxygen on response of living cells to X-rays with special emphasis on bacteria ALEXANDER HOLLAENDER, G E STAPLETON* AND F L MARTIN * *Biology Division, Oak Ridge Natl Lab, Oak Ridge, Tenn*

Suspensions of bacteria saturated with air are considerably more resistant to x rays if nutrient broth is used as a medium than when irradiations are done in physiological salt solution or phosphate buffer. If air is replaced by N_2 , the resistance of the bacteria increases manyfold, there being little difference if they are suspended in broth or salt solution. There is an increased response, with decrease of number, of bacteria in the suspension at low concentration ($<10^5$ bac/cc) as well as a decreased response with an increase of concentration of the broth. Five times as many roentgens are necessary to produce an equivalent killing effect when irradiations are done in the absence of oxygen than when O_2 is present. At 60,000 r the survival is 10,000- to 50,000-fold greater in N_2 than in O_2 . Similar but less pronounced effects were observed with fungi (*Aspergillus terreus*). There is very little, if any, effect at the energy

values used here if bacteria or fungi are added to the suspension after irradiation of the medium. In all experiments great care must be taken that the suspensions are well saturated with the gas under investigation. The moderate decrease of sensitivity of living cells to x rays by reducing the supply of air has been reported in a few scattered publications. Striking reduction in percentage of chromosome deletions in *Tradescantia* (GILES AND RILEY) and percentage of sex-linked lethals in *Drosophila* (BAKER AND SGOURAKIS) if air is replaced by nitrogen during irradiation, has been described from this laboratory.

Appetite studies in a patient with complete esophageal obstruction and jejunostomy FRANKLIN HOLLANDER AND HERBERT A. SOBER * *Gastroenterology Research Lab, Mount Sinai Hospital, New York City*

The subject was an ambulatory male, 18 years old, with cardio esophageal obstruction and jejunostomy for alimentation. He was fed our pre-digested aliment as the sole source of nutrition. Food was ingested orally, as prompted by appetite, but it never passed the esophageal obstruction and was regurgitated shortly after ingestion. Hence, the influence of daily intake of jejunal aliment upon body weight and appetite, measured by calories ingested orally, could be studied. The investigation of this and other phenomena lasted for about 15 years, during which time the subject was employed in the Laboratory specifically for this purpose. Three sets of observations, each lasting about one month, indicated that appetite is inversely—though not precisely—related to nutritional intake. Subsequent repetitions of these experiments, however, failed to confirm this, i.e. oral intake varied during constant jejunal intake, and sometimes the two were correlated directly. The latter was encountered during periods of overt emotional upset, not manifested during the earlier part of the study. In conclusion: 1) there is evidence that appetite diminishes as nutritional intake increases, even when no food can enter the stomach, 2) this relation may be upset and even reversed by emotional disturbances, 3) generalized inferences regarding physiological reactions of man, from observations on a single individual, must derive from extensive repetition of the experiments, and should preferably be held in abeyance until confirmed on other subjects. These precautions are particularly important for work with patients possessing gastrointestinal fistulae, because of the profound emotional disturbances frequently encountered in such cases.

Metabolic response to adrenaline of pre- and post-operated patients J. W. HOLLER, * A. DURY, R. BURTON, * E. H. KEUTMANN * AND C. SMITH *

Dorn Lab Med Research, Bradford Hospital, Bradford, Penna., and Depts. of Medicine and Surgery, Univ. of Rochester School of Medicine, Rochester, N. Y.

The effect of a single intramuscular injection of 0.4 ml. aq. adrenaline (1:1000) upon the plasma potassium, glucose, absolute eosinophiles and other blood constituents was measured in patients before and 3 days post-operative. The surgeries were of the type classed as minor operations. The percentage change in these blood constituents from the overnight-fast level was calculated for the periods of 4, 20, 60, and 120 minutes after an injection of adrenaline. The mean change levels in the surgical patients after adrenaline were compared with those calculated for normal adults and Addisonian patients after a like injection of adrenaline. The eosinophile response in the pre-operated group was similar to the normal adults 60 and 120 minutes after adrenaline. After surgery, the eosinophiles were unaffected by the adrenaline stimulus. The mean change in the blood sugar of the pre-operated and normal adult groups were comparable 20 and 60 minutes after adrenaline. The pattern of change after adrenaline in the blood sugar post-operative was similar to the Addisonians and of much lesser extent than the normals. The mean change in plasma potassium in the pre-operated patients was similar to, but of lesser extent, than in the Addisonians after the adrenaline injection in all the time periods. The mean changes in plasma potassium in the post-operated group after adrenaline were slightly above the preinjection level in all the time periods and suggest very little response to the adrenaline stimulus. These data indicate minor surgery can affect glucose and potassium metabolism, and the responsiveness of the adrenal (eosinophile decrease) to adrenaline stimulus to an extent comparable to that observed in Addisonian patients.

Induction of convulsions in rats STEVEN M. HORVATH AND G. M. AUSTIN * *Univ. of Pennsylvania, Philadelphia, and State Univ. of Iowa, Iowa City*

This paper deals with the effects of continuous radar pulsations at short distances on a group of 47 rats. The dorsal surface of the head was exposed to a wave length of 12.2 cm. for varying periods of time. Sixteen rats were exposed to a 60-watt energy output at 2.5 cm. distance, and 25 rats exposed to a 90-watt output at zero distance from the skull. In 6 rats the director was focused over the spinal cord. Those rats exposed to a 60-watt output showed clonic type convulsions in a mean time of 2.8 minutes. These rats had an average increase in rectal temperature of 4.2°F. Those exposed to 90-watt output convulsed in a mean time of 1.2 minutes. There was no generalized

hyperthermia in these rats. Brain temperature measured in 8 rats showed an average temperature of 110.4°F immediately after onset of convulsions, although in those exposed to 90 watts there was no associated increase in rectal or thigh muscle temperature. No pathological changes were found in any of the brains of sacrificed rats severe enough to explain the convulsions. Mild pyknosis, in the Purkinje cells of the cerebellum, in the Pyramidal layer of Ammon's Horn, and in the third layer of the cerebral cortex were the only findings outside of moderate congestion. It is suggested that a specific rise in the temperature of the brain itself is the most important factor in these convulsive attacks.

Possible renal vascular shunt in dogs during intravenous epinephrine C RILEY HOUCK *Division of Physiology, Univ. of Tennessee, Memphis*

Physiologic evidence for a shunting of blood from the cortex to the medulla of the dog kidney, 'Trueta shunt,' during the injection of epinephrine hydrochloride was sought using the clearance, tubular saturation and extraction techniques (renal vein catheterization via jugular vein), simultaneously wherever possible. In 14 dogs under Nembutal, doses of epinephrine from 21 to 81 γ /kg were given intravenously over a period of from 8 to 20 minutes. Mean blood pressure, renal resistance, renal extraction and consumption of oxygen and the hemoconcentration of renal vein blood were substantially increased to a degree proportional to the dose. Filtration rate, urine flow and renal blood flow were decreased to a degree proportional to the dose. The Tm of glucose was normal. The Tm of PAH at low doses was normal but 70% reduced at high doses. The filtration fraction (creatinine extraction) was elevated at low, depressed moderately at intermediate, and increased at high doses. Extraction of PAH was normal at doses from 21 to 67 but decreased 30% at 81 γ /kg. Since extractions of PAH, creatinine and oxygen, and the Tm's of glucose and PAH were not significantly decreased by moderate doses of epinephrine in the presence of a moderate to marked decrease in glomerular filtration rate, urine flow and renal blood flow, no appreciable shunting of blood from the kidney cortex to the medulla was indicated. Such an interpretation was less certain with larger doses.

A carbonyl reaction differentiating the fetal zona reticularis of the human adrenal cortex from the mouse X zone EVELYN HOWARD AND R. S. BENUA * *Dept. of Physiology, Johns Hopkins Univ. School of Medicine, Baltimore, Md.*
The involution of the X zone of the mouse adrenal cortex is a process which occurs after sexual maturity in females and earlier in males.

It has been suggested that the mouse X zone might be comparable to the human fetal reticularis primarily because its degeneration constitutes a spontaneous regression of a large part of the inner portion of the cortex, occurring apparently as a part of the normal maturation of the gland. The application of the histochemical technique of Ashbel and Seligman for the detection of lipoidal carbonyl groups has now revealed a clear-cut differentiation between these zones in mouse and human adrenals, in that the human fetal reticularis is strongly positive for the presence of lipoidal carbonyl groups, whereas the mouse X zone gives no indication of the presence of appreciable amounts of these compounds. This test substantiates histogenetic indications of differences between these adrenal zones. It is concluded that there can be no simple homology between the mouse X zone and the human fetal reticularis. The facts that the mouse X zone does not reveal free ketosteroid, and that it occurs as an independently proliferating part of the cortex, direct attention to the possibility that reticularis cells without free ketosteroid may have a special function, and are not merely waiting for senescence under all circumstances. The X zone has been further characterized in that it has been found to be markedly suppressed by a low protein diet on which body growth is reduced.

Effect of desoxycorticosterone and pitressin on the water balance of amphibia KUANG-MEI HSIEH (introduced by ROBERT GAUNT) *Dept. of Zoology, Syracuse Univ., Syracuse, N. Y.*

It has been demonstrated (Brunn) that frogs injected with posterior pituitary extracts show a temporary gain in body weight when in suitable environments due to the uptake of water. We have attempted to determine whether this action of posterior pituitary extracts in amphibians can be antagonized by administration of adrenal cortical steroids as can the effect of such extracts on water excretion in mammals. The uptake of water by *Rana pipiens* injected with 0.5 units of posterior pituitary extract (pitressin) has been confirmed. Three hours after injection control frogs had lost 0.17 gm while those receiving pitressin had gained 4.02 gm. Frogs injected with 0.1 or 0.2 mg of DCA showed no significant weight change when compared with untreated controls (untreated = -1.83 gm, DCA-treated = -0.42 gm). One ml of adrenal cortical extract (Upjohn) also was without effect. When frogs were injected with 0.2 mg DCA and 0.5 units of pitressin together there was a questionable potentiation of the action of pitressin by DCA. In order to determine the effect of pitressin and the adrenal steroids on the rate of water excretion, frogs were given distilled water (0.5 ml/10 gm body weight) by stomach tube and the

urine excreted was measured over a period of 9 hours Pitressin (0.5 units) caused a temporary inhibition of urine flow which lasted for less than 3 hours. Both DCA (0.2 mg) and cortical extract (1.0 ml) caused an inhibition of urine excretion which lasted over the 9 hour period of observation. When DCA and pitressin were given together there were no additive effects and the duration of action of DCA appeared to be reduced. It is apparent that the effect of these hormones in frogs differs markedly from that seen in mammals.

Blood volume studies at 5,280 feet altitude DAVID M. HUEY* AND JOSEPH H. HOLMES *Fitzsimmons General Hospital and Dept. of Medicine, Univ. of Colorado, Denver*

In view of the higher hematocrit values at this altitude (5,280 feet) studies of blood and plasma volumes were undertaken in 3 different groups. The first group a) comprised 50 active duty soldiers stationed at Fitzsimmons General Hospital (average age 27), the second group b) 32 male medical students (average age 28), and the third group c) 22 female hospital workers (average age 25). For the soldiers the plasma volume was 41.8 cc/kg, the blood volume was 80.7 cc/kg, and the hematocrit was 50.0%. For the medical students the plasma volume was 39.8 cc/kg, the blood volume was 77.0 cc/kg, and the hematocrit was 49.5%. For the female hospital workers the plasma volume was 41.4 cc/kg, the blood volume was 71.0 cc/kg, and the hematocrit was 44.1%. When compared with average values obtained by Gregersen and co-workers near sea level on 53 normal male medical students the effect of altitude would appear to be an increase in the percentage cell volume and hematocrit values and a decrease in the plasma volume. Values obtained for serum protein concentration and circulating protein per unit body weight were not significantly different from the values obtained by Gregersen near sea level.

Factors influencing active ion uptake by the isolated frog skin ERNST G. HUF *Dept. of Physiology, Medical College of Virginia, Richmond*

The net uptake of Cl^- , Na^+ , H_2O from Ringer's solution (R) by the surviving frog skin has been studied using skin bags. The bags (epithelium inside) were filled with 5 ml of R and immersed for 12 hrs in 2.5 l of R of the same concentration (*Federation Proc.* 8:78, 1949). Cl^- and Na^+ were determined iodometrically and flame photometrically respectively. After 12 hours amount and ion concentration of the fluid in the bag had diminished. The changes were dependent on salt concentration, pH and temperature of the R. The net uptake of ions and H_2O from 0.4 R (48×10^{-3} mEq Cl^- or Na^+ /ml) was only slightly less than the uptake from 1.0 R (120×10^{-3} mEq/ml).

The Cl^- and Na^+ gradients across the skin after 12 hours were higher in experiments with 0.4 R than in experiments with 1.0 R. Acid reaction of the R or lowering its temperature (3) decreased the net uptake of ions and H_2O from 0.4 and 1.0 R. In the majority of experiments more Na^+ than Cl^- was absorbed by the epithelium. The apparent Cl^- excess (Na^+ deficit) in the bag increased with increasing temperature. The solution touching the epithelium became more acid than the solution touching the chorion side of the skin. It can be calculated from QO_2 that enough acid metabolites are produced to combine with the apparently unbalanced amounts of Na^+ taken from and of Cl^- left over in the solution in the bag.

Muscle spindle excitation by efferent fibers in cat CARLTON C. HUNT* AND STEPHEN W. KUFFLER *Wilmer Institute, Johns Hopkins Med. School, Baltimore, Md*

Stimulation of small diameter (3-8 μ) nerve fibers which comprise 25-30% of the lumbosacral ventral root outflow in cat does not cause increased muscle tension. These nerve fibers influence the discharge from stretch receptors in muscle spindles, presumably by excitation of the muscle elements within the spindles, the intrafusal muscle fibers (Leksell, Kuffler and Hunt). The cat's small-nerve system therefore differs from that found in the frog where motor nerves of about 5 μ cause considerable tension by setting up localized contractions around the neuromuscular junctions (Kuffler and Gerard). The small-nerve effect on the afferent discharge from spindles was detected in various ways, particularly by stimulating individual efferent nerve fibers in the ventral roots while recording the discharges from a spindle in an appropriate single afferent nerve fiber in the dorsal root. When an efferent small-nerve fiber is stimulated repetitively (50-120/sec), it can produce in a single afferent fiber a response rate which, after a short period of facilitation, follows the stimulating rate. This 'driving' of the spindle discharge depends to a large extent on the external stretch applied to the muscle and not all units can be driven in such a manner. The efferent spindle response can be maintained by small-nerve excitation for long periods. A similar driving can be obtained by applying mechanical oscillations to the tendon or body of the muscle and certain stretch receptors can 'follow' a tuning fork vibration at 50-200/sec if the muscle is under appropriate external stretch. It is suggested that in both instances of driving the mechanism of excitation is similar. One may assume that the intrafusal muscle fibers, when stimulated through their nerves, can stretch and thus excite the sensory nerve endings within a spindle. This excitation is superimposed on that

already provided by a given external stretch. The most reasonable explanation of the above phenomenon appears to be that the intrafusal fibers in the spindles can respond with distinct tension increments to each small-nerve impulse at relatively high frequencies.

Development and loss of resistance to cell division blocking action of nitrogen mustards JOHN O. HUTCHENS AND BETTY PODOLSKY * *Dept. of Physiology and the Toxicity Lab, Univ. of Chicago, Chicago, Ill.*

Methyl, bis (β -chloroethyl) amine (HN-2) and tris (β -chloroethyl) amine (HN-3) at 10^{-6} – 10^{-4} M produce the following sequence of events when added to cultures of *Chilomonas paramecium* growing (logarithmic phase) in ammonium acetate media: 1) cell division continues until 30–50% of the cells have divided, 2) division then ceases for about two cell generation times (12–24 hours depending on temperature) the cells meanwhile growing larger, 3) the division rate briefly exceeds the control rate to which it finally returns. Resumption of division occurs while the medium contains active mustard as evidenced by the fact that previously unexposed cells exposed to it at this time are inhibited. Addition of freshly prepared mustard solutions to inhibited cultures about to resume division does not prevent or further delay division. This resistance is maintained if the cells are continued in a mustard-containing medium. Sensitivity to mustard action is regained (<3 cell generation times) when the cells are returned to mustard-free solutions. The observed effects are difficult to explain on the basis of genetic mutations. It seems more likely that the cells discover an alternate metabolic pathway for synthesis of a constituent critical for cell division. We have previously shown that HN-2 and HN-3 do not seriously affect respiration or carbohydrate metabolism in this range of concentrations. Protein, pentose nucleic acid and desoxy-pentose nucleic acid synthesis are all affected, however. It seems most likely that the critical constituent lies in one of these categories.

Effect of sustained elevation of renal venous pressure on sodium excretion in the unanesthetized dog W. HWANG,* L. AKMAN,* A. MILLER,* E. SILBER,* J. STANLER* AND L. N. KATZ *Cardiovascular Dept., Medical Research Inst., Michael Reese Hospital, Chicago, Ill.*

Influence of increased renal venous pressure (RVP) on sodium excretion was studied in 5 trained unanesthetized dogs. Renal plasma flow (RPF), glomerular filtration rate (GFR), and sodium excretion (with and without intravenous hypertonic sodium input loads) were studied

serially before and after partial ligation of the inferior vena cava just above the renal veins. Venous pressure distal to the ligation was consistently maintained at elevated levels of 250–350 mm of saline for at least 2 weeks postoperatively. The initial postoperative clearance studies (3rd day postoperatively) revealed the increased RVP to be uniformly associated with a depression of GFR and therefore with the amount of Na presented to the tubules. Under these circumstances, 3 of the dogs exhibited depressed Na excretion, while the other 2 showed normal Na excretion. Thus, depressed GFR was frequently, but not uniformly, associated with depressed Na excretion. Depression of GFR persisted for 5–8 days postoperatively, returning thereafter to control rates despite persistent elevation of RVP. Na excretion also returned to control levels. Thus under our experimental conditions, sustained increases in renal venous pressure did not necessarily cause reduction of sodium excretion. It would appear that no simple cause and effect relationship exists between chronic renal venous pressure elevation and Na excretion in the dog.

Effect of purified growth hormone on the glycogen content of tissues of the rat BARBARA A. ILLINGWORTH* AND JANE A. RUSSELL *Dept. of Physiological Chemistry, Yale Univ., New Haven, Conn.*

A single intraperitoneal injection of purified growth hormone (1–2 mg/100 gm body weight) into fasted normal adult albino rats results in an increased accumulation of glycogen in gastrocnemius, heart and diaphragm muscles at the end of 6 hours. This effect is observed in animals in which the fast is continued and in those fed glucose by stomach tube. The liver also shows an increase in the treated fasted rats. The magnitude of the net increase can be accounted for by assuming a decreased catabolism of carbohydrate. The minimal effective dose in glucose-fed animals was of the order of 100 γ /100 gm for several different preparations of hormone. That the action of growth hormone on carbohydrate metabolism is probably not mediated through an increased secretion of insulin is indicated by the following: a) The minimal effective dose of growth hormone is not hypoglycemic, b) a dose of insulin (0.1 μ protamine zinc insulin/kg) resulting in a hypoglycemic response similar to that due to the higher dose of growth hormone fails to augment the glycogen content of tissues other than the diaphragm, and c) the respiratory quotient is depressed by growth hormone and elevated by insulin administration. Experiments with adrenalectomized rats fed glucose showed that whereas neither growth hormone nor a minimal dose of A.C.E. (0.5 cc of Wilson's aqueous ex-

tract) alone have any effect, simultaneous treatment results in a significant elevation of carbohydrate stores

Comparison of effects of a stress on the glycosuria of force-fed partially depancreatized and of partially depancreatized-adrenalectomized rats

DWIGHT J INGLE *Research Labs, Upjohn Company, Kalamazoo, Mich*

The activation of the adrenal cortices during stress might be expected to intensify the diabetes of partially depancreatized rats. To the contrary (Ingle, in press), the injection of toxic amounts of formaldehyde caused some decrease in glycosuria. In the present experiments on 40 mildly diabetic rats, 20 were adrenalectomized and treated with amounts of adrenal cortex extracts (ACE) which sustained the pre-adrenalectomy level of glycosuria. Subcutaneous injections of 1.5% formaldehyde were made twice daily in doses of 0.25, 0.5 and 1.0 cc for periods of 7 days and of 0.25 cc for 28 days in both adrenalectomized rats. The animals were force-fed a medium carbohydrate diet. All rats showed a decrease in glycosuria during stress, but the fall was more striking in the adrenalectomized rats. These data support the hypothesis that the increased secretion of adrenal hormones during stress goes to meet an increased 'need' and tends to maintain homeostasis rather than to represent hypercorticalism. The increased cortical activity during the stress did have a positive effect upon carbohydrate metabolism in that it tended to prevent the fall in glycosuria noted in the adrenalectomized rats whose intake of cortical hormones was uniform.

Nature of influence of pH on hemolysis by sodium oleate

M H JACOBS AND CAROLYN STOUT *
Dept of Physiology, Univ of Pennsylvania School of Medicine, Philadelphia

The peculiar nature of the pH dependence of sodium oleate hemolysis illustrates the manner in which the interaction of several factors, each in itself relatively simple, may lead to situations which when not properly analyzed appear to be hopelessly complex, difficult to reproduce, and at times bizarre. Three such factors have so far been separated by the methods here employed. The first is a direct effect of the oleate on the cell surface, leading to a condition of free cation-permeability, within a pH range of approximately 6-8 it decreases with increasing pH. The second is the swelling of the cation-permeable cell through the operation of the Donnan ionic equilibrium, this is greatest at the acid and alkaline ends of the range and least near its middle. The third is a 'protection' of the altered cells, apparently by interfacial layers of oleate, which prevent the escape of hemoglobin under conditions where it would otherwise occur. This effect is favored by

acidity, and is opposed, or may even be reversed, by alkalinity. The interaction of the 3 factors is influenced not only by the pH of the medium but by the concentration of the oleate, the number of cells on which a given amount of it may act and the temperature. Other things being equal, the effect of any given pH change depends on its simultaneous, and in general dissimilar influence on the three factors in question, and possibly on others of an as yet unknown nature.

Structure of gels from ovalbumin and serum albumin

MARTIN P JAGGI* AND DAVID F WAUGH
Dept of Biology, Massachusetts Inst of Technology, Cambridge, Mass

Gels have been prepared from Armour crystalline ovalbumin and serum albumin. *Ovalbumin* Appropriate combinations within the ranges 0.5 to 7%, pH 4.2 to 2.4, ionic strength less than 0.01, will yield gels when heated for 2 minutes at 100°C. Above 1% protein gels form over a small pH range (at 2% protein pH 4.3-4.7) which decreases as the protein concentration increases. Electron micrographs of viscous solutions prepared by heating 0.01% protein at pH 4.4 reveal fibrous networks whose strand width is approximately 200 Å. Reversion of 2% gels by sodium hydroxide at pH 11.0 and 23°C for 10 minutes produces products resembling native ovalbumin in molecular weight and gel-forming properties. *Serum Albumin* Appropriate combinations within 1-8% protein, pH 4.15-3.9 and ionic strength 0.1 (acetic acid buffer) yield gels when heated for 2 minutes at 100°C. Several gels show strong static double refraction. Electron microscope examinations were made on 4% gels centrifuged at 240,000 g for 120 minutes and dispersed by ultrasonic treatment. The specimens were faintly shadow cast with chromium. Dispersed fibrils with approximate dimensions 200 × 2000 Å were observed. Alkaline reversions of the original gels gave products resembling the native protein. The basic structure of both gels appears to be a cross-linked system of fibrils. Although reversion products have not shown to be identical with initial protein they suggest that individual fibrils may be constructed of corpuscular units.

Maturation of pituitary-adrenal axis in the newborn rat

JOSEPH W JAILER *Depts of Medicine and Obstetrics and Gynecology, Columbia Univ College of Physicians and Surgeons, New York City*

Exposure of adult rats to stress results in an almost immediate fall in adrenal ascorbic acid in intact but not in hypophysectomized animals. The administration of adrenocorticotrophic hormone produces the same effect without regard to the absence or presence of the animals' pituitary (LONG, SAYERS *et al*). The purpose of this in-

vestigation was to determine whether the pituitary-adrenal axis can be similarly stimulated in the newborn rat as it is in the adult. The subcutaneous administration of 0.04-0.05 mg of epinephrine to infant rats, 2, 4 or 6 days of age, fails to cause a decline in adrenal ascorbic acid. At 8-10 days of age, the same procedure results in a fall of approximately 30% in adrenal ascorbic acid. Rats 4, 6, 7, 11 and 14 days of age were refrigerated at 5°C for from 75-100 minutes without producing any alteration in adrenal ascorbic acid. However, 16- and 25 day old rats exposed to the same experimental conditions responded with a 20% decline in adrenal ascorbic acid. When rats 1, 4 and 6 days of age are treated with ACTH they respond with a decrease in adrenal ascorbic acid of about 30%. Consequently, it would appear that when exposed to stress the newborn rat's pituitary cannot respond by liberating adrenocorticotrophic hormone but their adrenals are capable of responding to exogenous ACTH. Further evidence has also been adduced which shows a lack of response to stress in the newborn rat, as compared with older animals.

Relation of urinary pepsinogen excretion to gastric secretory activity in man HENRY D. JANOWITZ* AND FRANKLIN HOLLANDER *Gastroenterology Research Lab, Mount Sinai Hospital, New York City*

The relationship between gastric secretory activity (HCl and pepsin) and urinary pepsinogen excretion in man was studied by simultaneous complete collection of gastric secretion and urine. It is generally held that a parallelism exists, but this is inadequately supported. Sixty-one subjects, with a wide range of gastric secretory levels, were employed for this study. Some of these were ulcer patients. Simultaneous collection of unstimulated gastric juice and of urine was made under resting conditions for periods of 3 hours. Gastric pepsin activity was measured by Bucher's modification of the Anson-Mirsky method, adapted recently in this Laboratory to a lyophilized hemoglobin substrate, and was expressed in terms of mEq of tyrosine liberated. Uropepsin was measured by I. A. Mirsky's modification of this procedure. HCl was measured by colorimetric titration. The production of acid and pepsin, and excretion of uropepsin were calculated in terms of average hourly output. In these subjects, the gastric acid output ranged from 0 to 7.9 mEq/hr, the pepsin output from 0 to 21,219 units/hr, the urinary pepsinogen output from 0 to 373 units/hr. In these ranges the excretion of urinary pepsinogen varied directly with gastric pepsin output, this supports the concept of an exocrine-endocrine partition of gastric pepsinogen and justifies the use of uropepsin determinations

as a measure of gastric enzyme secretory activity under resting conditions. The correlation of acid and pepsin outputs in the interdigestive phase may account for the association of acid production and uropepsin output noted by others. These relations will be evaluated statistically.

Comparison of pressure and flow pulses in the unopened carotid artery of the dog KENNETH E. JOCHIM *Dept. of Physiology, Univ. of Kansas, Lawrence*

Flow pulses were recorded from the unopened carotid artery of anesthetized dogs by means of the electromagnetic flowmeter. Pressure pulses were recorded simultaneously from the same point in the artery with a Lilly capacitance manometer by introducing a fine catheter into the vessel through a small branch. Control records in different animals consistently showed that the systolic rise began simultaneously in both pressure and flow pulses, but that maximum flow was reached earlier than maximum pressure. The incisural drop in flow was relatively greater in magnitude than the corresponding drop in pressure. The diastolic portion of the flow curve was more variable than that of the pressure curve, sometime it presented a very gradual descending slope, and occasionally a prominent positive wave was evident. In some animals a momentary backflow occurred at the end of systole. Epinephrine in doses ranging from 0.5 to 10.0 gamma/kg decreased mean carotid blood flow, the larger decreases (more than 50%) occurring with the larger doses. The ratio mean carotid pressure/mean carotid flow was increased, sometimes by more than 300%, for periods of 8 minutes or more. Histamine intravenously in doses of 100 gamma/kg decreased the carotid flow by as much as 66% and reduced the pressure/flow ratio by almost the same percentage. Both flow and pressure pulses were altered in such a way that they became almost exactly superimposable.

Effect of theophylline, theophylline ethylenediamine and 8-chlorotheophylline on electrocorticogram of rabbits R. J. JOHNS* AND H. E. HIMWICH *Medical Div, Army Chemical Center, Md*

Theophylline, theophylline ethylenediamine, and 8-chlorotheophylline were administered i.v. to locally anesthetized, curarized, artificially respired rabbits and electrocorticograms and electrocardiograms were recorded from monopolar electrodes with a 4-channel Grass electroencephalograph. Preliminary experiments showed that with low rates of injection it required more drug to produce seizures than was required at high injection rates. Furthermore, at very low rates (about 1 mg/kg/min) no amount of drug would invoke seizures. For that reason the rates of in-

jection were based on animal's weight and theophylline content of the drug, being 4 mg/kg/min for theophylline, 5 mg/kg/min for theophylline ethylenediamine, and 4.75 mg/kg/min for 8-chlorotheophylline. With theophylline and theophylline ethylenediamine grand mal-like cortical seizures were obtained at comparable dosages (156 mg/kg of theophylline and 204 mg/kg of theophylline ethylenediamine which is equivalent to 163 mg/kg of theophylline). 8-chlorotheophylline produced no changes in the electrocorticogram at this rate of administration, nor did it produce seizures when given more rapidly and in much larger doses (up to 1333 mg/kg). Further work is being done to investigate the marked difference between 8-chlorotheophylline and the other 2 drugs, whether due to pharmacological inactivation from chlorination in the 8 position, low solubility, or to an inability to permeate the blood-brain barrier.

Inhibition of luminescence by homologous series of carbamates FRANK H. JOHNSON, RICHARD SIMPSON,* ELIZABETH A. FLAGLER* AND KATHERINE MCGEER* *Biological Lab., Princeton Univ., Princeton, N. J.*

The action of a representative series of carbamates from n-methyl to n-octyl, as well as some other derivatives, on bacterial luminescence was studied in relation to drug concentration, temperature and hydrostatic pressure. At low temperatures and normal pressure, each caused a reversible inhibition involving a ratio of between 1 and 2 carbamate molecules/enzyme molecule, and the concentration required for a given inhibition appeared directly related to the activity coefficient of the derivative, from methyl to butyl but not all the way to octyl carbamate. The amount of inhibition at a given concentration was variously affected, among the different derivatives, by a rise in temperature. The data indicated that a given carbamate formed multiple equilibria with the enzyme affected, the predominant equilibrium depending upon conditions of drug concentration, temperature and pressure. At optimum temperature, pressures up to 8,000 lbs/sq. in decreased initially moderate inhibitions by methyl, ethyl or propyl carbamates, had little influence on moderate inhibitions by butyl or amyl carbamates, and increased the initially moderate inhibitions caused by hexyl or octyl carbamates.

Ether concentration in gas and blood samples obtained during anesthesia in man and analyzed by mass spectrometry CECIL S. JONES,* EDWARD J. BALDES, AND ALBERT FAULCONER, JR.* (with the technical assistance of JOHN SAARI)* *Mayo Clinic, Rochester, Minn.*

Various authors reporting on the concentrations of ether in respired gas mixtures, on the concentra-

tion of ether in arterial and venous blood, and on the ratio between the concentrations of ether in a blood and a gas phase at equilibrium (distribution ratio), have presented conflicting values for such measurements during ether anesthesia in animals and in human beings. As a preliminary to further study of these problems, methods of utilizing the mass spectrometer for qualitative and quantitative analysis for di-ethyl ether in samples of gas and blood were evolved. These methods require refinement to increase their accuracy. They were applied to the determination of ether concentrations in samples drawn from 10 surgical patients receiving ether anesthesia and to the determination of the *in vitro* values for the distribution ratio. The results so obtained do not depart too widely from the generally accepted figures given in standard tests. Values for the distribution ratio for ether for the samples of blood from 14 subjects ranged between 12.2 and 16.9. Between the thirtieth and sixtieth minutes of ether anesthesia, the concentrations of ether in arterial blood varied with the depth of anesthesia, between 78 mg and 153 mg ether/100 ml of blood. The mean value of 100 mg ether/100 ml venous blood falls within the extremes reported for man in respect to concentration of ether. Concentrations of ether in the inspired gas mixture varied, the mean value being 8.5 volumes of ether vapor %. Analysis of samples of tracheal air showed that the inspired ether mixtures were diluted in their passage toward the lungs.

Effects of excess potassium followed by Ringer's solution on responses of skeletal muscle ARTHUR J. KAHN* AND ALEXANDER SANDOW *Washington Square College of Arts and Sciences, New York Univ., New York City*

The current studies are a continuation of research previously reported (Federation Proc. 8:177, 1949). Muscles immersed in a 48 mg % K Ringer's solution produce a depth (R) of latency relaxation in isometric twitches which within 4 minutes is 270% of normal and then rapidly decreases to zero in about 50 minutes. Tension output (T) shows a similar time course, although the initial increase is only 25%. We interpret the immediate enhancing effects on R and T as an indirect consequence on the contractile system of the direct action of K on the membranes of the muscle fibers, and the later depressant effects as due to penetration of K and its direct action on the contractile system. When a muscle is immersed in the K-enriched solution for 4 minutes, thus developing the enhanced R and T responses, and is then returned to normal Ringer's, the enhanced effects are nevertheless maintained always above normal, though with some decreases, for about 2 hours. The continuance of the enhanced respon-

ses of the muscle in Ringer's after the initial K-treatment indicates 1) that the initial K-treatment has resulted in some relatively permanent alteration of the system responsible for generation of the latent relaxation and tension output, and 2) that the absence of the depressant effects is evidence that their production, when the K acts continuously beyond the initial 4-minute interval, is due to its penetration and thus direct action on the contractile system

Enzymatic activity of surface denatured catalase

J GORDON KAPLAN (introduced by W W WALCOTT) *Dept of Zoology, Columbia Univ, New York City*

That a 'surface-denatured' enzyme may retain its enzymatic properties has already been demonstrated for the pepsin-albumin system. An intracellular enzyme, catalase, was studied for activity in the surface-denatured state, since this class of enzymes probably exists within the cell at the surface of cellular structures. A suspension of crystalline beef-liver catalase buffered at pH 6.9 was placed drop-wise on the air-water interface of a Langmuir trough buffered at the same pH, allowed to form a monolayer and then compressed into a solid fiber (Devau effect) which was lifted from the trough by a needle. These fibers, after washing, were the site of a vigorous bubble formation when they were covered with a dilute H_2O_2 solution, after heating at $100^\circ C$ for a few minutes all their activity was lost. A comparative study of the effect of temperature on the enzyme in solution vs the enzyme as fiber revealed a striking difference between the two. Heating at $50^\circ C$ up to 4 hours increases the activity (residual) of the fiber, whereas it decreases the activity of the catalase in solution. All measurements were made in the Warburg respirometer. The evidence permits the following conclusions: a) The change in behavior of the fiber is due to its altered physical properties, and b) The difference in behavior suggests that it is the fiber, not contaminating native molecules in solution, which possesses the enzymatic activity.

Testicular and crystalline hormone implants in the rat seminal vesicle

SEYMOUR KATSH (introduced by HARRY A CHARIPPER) *Washington Square College, New York Univ, New York City*

Testis autografts (averaging 2.5 mg) and homografts (averaging 11.6 mg, from 15-day-old rats) serve to maintain the reproductive accessories of castrated adult hosts which receive these transplants to the seminal vesicle. The criteria employed are weights, and histological and cytological evidence of stimulation of the vesicular-prostate complex. The greatest androgenic effects are seen in closest proximity to the grafts. Micro-

scopic examination of the serially sectioned implanted-vesicles reveals the autografts to be more severely disorganized than the homografts. Implants of pancreatic, salivary, thyroid, fetal membrane, and placental tissues and cholesterol, estrone and progesterone crystals have no androgenic effects as measured by the three above-mentioned criteria, but the efficacy of testosterone propionate is well demonstrated since each vesicle receiving these crystals weighs more than twice the normal and shows more intense cytological activity. The contralateral vesicles and ventral prostates of the testosterone-implanted animals are morphologically and histologically normal. Thus the results of the testicular and testosterone series indicate the establishment of an androgenic field with greatest potency at the site of implantation. In the testicular series a tall columnar epithelium is found close by the graft while more distantly a low epithelium is seen, the testosterone-treated vesicles are at least twice as large as their mates. Previous studies with adrenal and ovarian implants support these results.

Effect of intravenous hydrochloric acid-amino acids on plasma chloride

YALE J KATZ (introduced by GEORGE E FAHR) *Clinical and Lab Service, St Barnabas Hospital, Minneapolis, Minn*

Occasions arise when it is desirable to administer intravenously the chloride ion without the use of the sodium ion. Significant amounts of chlorides cannot be given in the form of free hydrochloric acid. A mixture of 0.05 molar HCl and a 5% commercial protein hydrolysate was found to have a pH of 4.0, and 0.10 M HCl in 5% amino acid to have a pH of 3.3, while unbuffered 0.05 N and 0.1 N HCl are pH 1.4 and pH 1.1 respectively. Commercial protein hydrolysate with 3.3 gm HCl added per liter was injected into the ear vein of the rabbit, in an amount of 20 cc/kg. The plasma chloride content was increased an average of 24 mg % (Expressed as NaCl it would be 39 mg %). Proportional rises were found with repeated injections. Since amino acids are metabolizable the chloride remains in excess. A decrease in the alkaline reserve results. This type of solution should provide the clinician a means of simultaneously treating hypochloremia and alkalosis.

Age and serum cholesterol concentration in normal man

ANCEL KEYS, OLAF MICKELSEN, RUSSELL HAYES* AND ERMA V O MILLER* *Lab of Physiological Hygiene and the Students Health Service, Univ of Minnesota, Minneapolis*

Serum total cholesterol concentrations were measured in 2050 urban Minnesota students, business and professional men who were found clinically normal in detailed examinations. Both Liebermann-Burchard Bloor extract and Sperry-

Schoenheimer digitonin methods were used without significant differences between results. For 1114 males from 17 through 45 the relation holds $Y = 126.8 + 2.35X$, $E_b = \pm 0.18$, where Y = cholesterol mg %, X = age, E_b = standard error of the slope. For 287 males 45 through 55 years the equation is $Y = 187.9 + 1.21X$, $E_b = \pm 0.71$. For 52 males aged 55 through 78 the equation is $Y = 476.6 - 3.86X$, $E_b = \pm 0.75$. These slopes are all significantly different. For 564 females aged 17 through 30 years we have $Y = 134.4 + 1.98X$, $E_b = 0.43$, compared with $Y = 126.0 + 2.39X$, $E_b = \pm 0.33$ for 1025 males of the same ages. For age 22.0 years estimated values for males and females are, respectively, mean = 178.7, 177.8, S.D. = ± 33.9 , 31.2, S.E. = ± 1.06 , 1.31. The least-squares equation for 30 normal boys aged 6 through 12 is $Y = 176.1 + 1.19X$, $E_b = \pm 2.91$. For all ages the standard deviations are between 24 and 36 mg %. The data demonstrate a marked curvilinear relation, with minimal values in late adolescence, maximal values in the 50's, and progressive decrements in old age. Preliminary norms and fiducial limits are established for ages 17 through 78 (females 17 through 30) for comparable populations. For ages 20, 30, 40, 50, 60, and 75, the means are, respectively, 173.8, 207.3, 230.8, 248.3, 267.0, and 202.1.

Further studies on prophylaxis and therapeutics of experimental renal hypertension with renal extracts J. P. KIELY,* J. M. KIELY,* BESS G. OSGOOD,* JOHN MARSHALL* AND G. E. WAKERLIN *Univ. of Illinois College of Medicine, Chicago*

During the past 10 years our research has conclusively demonstrated that certain renal extracts are very effective in the treatment and prophylaxis of experimental renal hypertension in dogs. During the past year the following progress was made toward determining the mechanism of the antihypertensive action and toward achieving optimal methods of extraction. Of 5 renal hypertensive dogs treated with crude hog renal cortex extract containing renin 2 showed good, one questionable, and 2 no reductions in blood pressure. Of 4 renal hypertensive dogs treated with semi-purified hog renin (70 DU/mg N) 2 showed good and 2 no reductions in blood pressure. Prophylaxis of 4 dogs with crude hog renal cortex extract containing renin was successful in 3 of the animals. The results suggest that a 48-hour aqueous extract of acetone-ether desiccated and defatted hog renal cortex powder is less effective than a 16-hour extraction, that a previous course of extract of whole hog kidney interferes with the therapeutic effect of crude hog renal cortex extract containing renin and of semi-purified hog renin, and that anti-renin may be involved in

the therapeutic and prophylactic effects seen. Renal clearance studies strongly suggest that the therapeutic and prophylactic effects were not due to changes in glomerular filtration rate or renal blood flow. We are now conducting further therapeutic and prophylactic experiments with semi-purified hog renin (for which a high yield method of preparation has been developed), with crude hog renal cortex extract containing renin, and with hog renal medulla extract.

Psychomotor aspects of the orbitofrontal cortex H. E. KING (introduced by CARNEY LANDIS) *Dept. of Research Psychology, New York State Psychiatric Inst., New York City*

In an investigation of the effects of frontal lobe damage upon higher motor functions in the human it has been found that the surgical procedures of prefrontal venous ligation (the bilateral occlusion of all the cortico-dural veins visible between a point 2 cm. caudal to the tip of the frontal pole and a point 2 cm. caudal to the coronal suture), superior topectomy (the bilateral excision of Brodmann's cortical areas 9, sometimes 10, 8 and 32) or orbital topectomy (bilateral excision of areas 11, sometimes 47, 10 and Walker's 13) all significantly decreased motor performance when measured at a period 10 days after operation, but measures made 3 months after operation revealed the patients to again perform at their preoperative level of ability. Measures have been made of response time, speed of continued movement and movement dexterity upon these operative groups. When all cases (24) were considered together the reduction in performance following operation was approximately 15%, and was statistically significant. When different operative subgroups were considered separately they were seen to be affected differentially, with the superior topectomy cases showing the greatest temporary reduction, prefrontal venous ligation cases showing the next greatest reduction and the orbital topectomy cases showing the least interference with performance. It appeared unlikely that these reductions could be explained in terms of general post-operative sluggishness and inattention since no such alteration was noted in a large number of sensory tests administered at the same testing intervals which required close attention for their adequate performance. It would appear that operations involving the orbitofrontal cortex constitute a temporary interference with a motor integrative system at the higher levels, this interference being greater when the damage is on the superior surface of the brain.

Longevity as a function of diet in the C3H mouse JOSEPH T. KING AND M. B. VISSCHER *Dept. of Physiology, Univ. of Minnesota, Minneapolis*
Several workers have reported increased life

span in rats and mice on caloric restriction In this study C3H males were used in order to avoid the problem of mammary cancer The mice were housed individually, put on the diets at weaning, and kept in an air-conditioned room One group was fed *ad libitum* on commercial chow, the other three groups were given the semi-purified diet described by Visscher *et al* A control group was fed *ad libitum* One restricted group received approximately 66% of the normal caloric intake, with normal protein, vitamin and mineral intake The other restricted group received approximately 50% of normal caloric intake with about 15% restriction of protein, vitamins and minerals The group on 33% restriction had the longest life span (av 755 4 days) Those on 50% restriction followed (av 652 9 days), the controls were next (av 623 5 days) Those fed commercial chow showed the shortest life span (av 585 8 days) Moderate caloric restriction results in the greatest life span

Hemolysis by intracellular crystal formation

BRUNO KISCH *Fordham University and Marine Biological Laboratory, New York City and Woods Hole, Mass*

In eels caught in a deadly sick condition a kind of hemolysis was observed up to now unknown in hematology One or more crystals of prismatic shape developed in red blood cells, there stretching and growing up to twice the length of a normal erythrocyte, finally rupturing the cell membrane These crystals are not hemoglobin but are soluble in water In the polarizing microscope the extinction occurs at 90° It is supposed that an infectious disease, probably a virus infection, is the reason for this type of hemolysis

Ventricular complex of the electrocardiogram of birds BRUNO KISCH *Mount Sinai Hospital and Yeshiva Univ, New York City*

Previous literature on birds states that the electrocardiogram of birds has no *R* but only a deep *S* as main ventricular initial deflection In 20 experiments seagulls and chickens were investigated and the following results were obtained The usual extremity leads, taken with needle electrodes show left axis deviation with a very low voltage in Lead *I* Leads *II* and *III* are very similar to each other A small *R* and a deep *S* is nearly always present in Leads *II* and *III* *T* is upright in *II* and *III*, very low in *I* Chest leads taken in the level of the ventricles with Wilson's Central Terminal, show at the right side of the chest no *R* as a rule but a *QS* Those from the left side of the chest show an *rS* always Direct V-leads show a *QS* on the pectoral surface of the right ventricle, a small *R* and deep *S* on the left ventricle and a *QS* on the dorsal surface of the ventricle *T* is diphasic, often with a quick deep final phase

Inside each of both the ventricles and auricles the ventricular complex starts with a high upstroke (*R*) In most cases there is no, or a very small, *S*, and always an inverted *T* The same type of ventricular cardiogram can be registered from the surface of both auricles and of the aorta The ventricular complex in the unipolar extremity leads is characterized by a high *R* in the *VR* potentials Because these high *R* waves exist nowhere on the surface of the ventricle of the investigated birds but are typical for both cavity potentials, this is a proof that the right arm potentials really reflect the cavity potentials of the ventricle By changing the position of the heart the *R* in the right and left arm potential can be changed too The average of the heart rate of 12 chickens was 380, their rectal temperature was between 107° and 109°, the average heart rate of 8 seagulls was found to be 450 and the temperature between 104 5° and 106° Auricular fibrillation can be produced in birds by local application of acetyl choline on the auricles

Analysis of retrograde conduction to the atria from premature ventricular contractions, a common occurrence in the human heart ALBERT D KISTIN* AND MILTON LANDOWNE *Cardiovascular Research Unit, Veterans Admin, Washington, D C*

Retrograde conduction to the atria from premature ventricular contractions, generally considered rare, was demonstrated in 15 of 33 unselected individuals by means of esophageal electrocardiographic leads, although rarely detectable in a simultaneous lead *II* In esophageal leads *P* waves due to retrograde conduction occur within a limited range of time (0 09-0 46 sec) following the premature *QRS* They differ in contour from sinus *P* waves and/or are premature In the latter case the interval to the next sinus *P* wave is longer than a sinus *P-P* interval Atrial fusion complexes occur *Ventriculoatrial conduction time* is not consistently greater than atrioventricular conduction time Thus there is no evidence for 'normal' unidirectional block in the human In two cases where analysis was possible, ventriculoatrial conduction time varied directly with the degree of prematurity of the ventricular contraction and inversely with the sinus rate This suggests relative refractory period and vagal influence upon retrograde conduction, similar to conditions governing normal antegrade conduction In addition, there were two discontinuous orders of magnitude of ventriculoatrial conduction, differing by 0 11 sec in one case and 0 23 sec in the other, two retrograde pathways were hypothesized The limited degree of prematurity of retrograde atrial activation following an antecedent premature ventricular contraction, favors spontaneous dis-

charge of the sinus node which may explain the 'compensatory pause' frequently observed. In some cases, however, retrograde atrial activation was sufficiently premature to invalidate this explanation, and in these the 'compensatory pause' is unexplained or fortuitous.

Protein content and tryptic activity determined by several methods in canine pancreatic juice under different conditions of stimulation S A KOMAROV, HERMAN SIPLET* AND HARRY SHAY Samuel S Fels Research Inst, Temple Univ School of Medicine, Philadelphia, Penna

Protein content was determined by trichloroacetic acid precipitation (KOMAROV, S A, G O LANGSTROTH AND D R McFAE, *Canad J Research* 17 113, 1939), tryptic activity was determined after activation with various enterokinase preparations by 1) a modification of Mett's method (METT, S G, *Diss St Petersburg*, 1889), 2) by the method of TOMARELLI, R M, J CHARNEY AND M L HARDING *J Lab & Clin Med* 34 428, 1959, and 3) the photoelectric method of Riggs and Stadie as adopted by FRIEDMAN, M H F, *Gastroenterology* 7 526, 1947, for pancreatic juice. In dilution experiments with different types of pancreatic juice obtained in acute experiments 1) after secretin alone, 2) secretin and 'urecholine' stimulation and 3) postprandial secretion from dogs with chronic pancreatic fistula, only Mett's method gave a rectilinear relationship consistently over a wide range of dilutions up to 1:20. Results with the other methods gave a rectilinear relationship for velocity constants only over a narrow range of dilutions and even then not consistently (<50% of the experiments). In experiments with secretin alone and with Urecholine stimulation superimposed Mett's method showed a better correlation between protein content and units of tryptic activity (coefficient of variation from 14.7 to 33.3%) than did the Tomarelli method (C V = 11.8% to 123.2%) or Friedman's adaptation of the Riggs and Stadie method (C V = 14.4% to 54.6%). Urecholine in wide range of dosage when superimposed on secretin stimulation consistently produced a significant increase in the output of enzymes when measured by the output of protein nitrogen or by the Mett method, while the other methods failed to show this increase in some experiments.

Effect of inhalation of oxygen at high partial pressure upon cerebral circulation and cerebral oxygen consumption in man R H KOUGH,* D Y COOPER, JR,* G L ENMEL,* H H LOESCHKE,* C J LAMBERTSEN* AND C F SCHMIDT Lab of Pharmacology, Univ of Pennsylvania, Philadelphia

To measure the effects of high tensions of inspired oxygen on cerebral blood flow (CBF), cere-

bral oxygen consumption ($CMRO_2$) and cerebral vascular resistance (CVR) 3 groups of healthy young men were studied by the nitrous oxide method of Kety and Schmidt. Group 1 (6 subjects), the control group, breathed dry air through a demand regulator for one hour. Measurements A were made at the beginning and measurements B were made at the end of the one-hour period. The conditions of Group 2 (8 subjects) differed from those of Group 1 in that 100% oxygen was substituted for air after measurements A were made. The conditions of Group 3 (6 subjects) differed from those of Group 2 in that the last 15 minutes of oxygen breathing were at an ambient pressure of $3\frac{1}{2}$ atmospheres. Group 3 was considered to be in the preconvulsive stage of acute oxygen toxicity when measurements B were made. Means of measurements are tabulated below in terms of 100 gm of brain/min.

	GROUP 1		GROUP 2		GROUP 3	
	A	B	A	B	A	B
CBF (cc)	56	53	55	47	58	43
$CMRO_2$ (cc O_2)	3.3	3.1	3.4	3.5	3.4	3.5
CVR (mm Hg/cc)	1.3	1.3	1.2	1.5	1.1	1.6

The table indicates that a high tension of inspired oxygen, either directly or indirectly, may cause a decrease in cerebral blood flow, an increase in cerebral vascular resistance, but no appreciable change in cerebral oxygen consumption.

Valves of the hamster caecum HUGO KRUEGER AND RUDY RIESCHEL, JR * Dept of Zoology, Oregon State College, Corvallis

The caecum of the hamster is slightly sacculated and divided into an apical and a basal portion. Internally, this division is marked by a semilunar valve and externally by a groove in the wall of the caecum, the groove corresponding to the fixed border of the semilunar valve. At least 4 valves can be found in the caecum of the hamster: the ileo-caecal valve, an apico-basal semilunar valve, a basal semilunar valve and a chevron valve. The ileo-caecal valve located at the ileo-caecal junction has a semilunar lip which projects into the lumen of the ileum. The apico-basal semilunar valve is located immediately on the apical side of the ileo-caecal junction. This valve projects into the lumen of the caecum and may be considered as a continuation of a portion of the ileal wall into the caecum. Aided by partial constriction of the caecum the apico-basal semilunar valve could presumably prevent caecal contents from reaching the apex of the caecum and as a result the contents coming from the ileum would be shunted into the colon. The basal semilunar valve is parallel with

the apico-basal valve and is located about 5 mm toward the colon from the apico-basal semilunar valve. The chevron valve at the caecal-colonic junction is formed by the terminations of the many ends of muscular chevrons found in the colon. The first of these chevrons projects into the caecal lumen and forms a pocket on the caecal wall.

Preparation and physical properties of crustacean sinus gland hormone. ELOISE KUNTZ (introduced by RUTH E. CONALIN) *Brown University, Providence, R. I., and Vassar College, Poughkeepsie, N. Y.*

A method of isolating crustacean sinus gland hormone from extracts of evertalks by repeated adsorption on Norite A has been developed. Elution is accomplished with 10% NH_4OH in 50% ethanol at 70°C. The preparation causes expansion of the dark chromatophores of *Uca minax*. It is also effective in prolonging the life of evertalkless *U. minax* when given in frequent injections. The preparation exhibits ultraviolet absorption peaks at 280-285 and 335-340 $\text{m}\mu$. Measurements of relative fluorescence intensity at different hydrogen ion concentrations reveal a broad peak extending from pH 2.5 to 6.5 in the presence of phosphate.

Unipolar electromyograms of patients with dermatomyositis. E. H. LAMBERT, SIBYL BECKETT,* C. J. CHEN* and L. M. EATON* *Sections on Physiology and Neurology, Mayo Foundation and Mayo Clinic, Rochester, Minn.*

The electrical activity of muscle in 15 patients with dermatomyositis was detected with unipolar needle electrodes and recorded by a cathode-ray oscilloscope. In resting muscle, numerous potentials indistinguishable from single-fiber potentials occurred spontaneously. There was also increased irritability to needle movement. In voluntary contraction, muscular weakness was associated primarily with a decrease in size (amplitude and duration), rather than in number of motor-unit action potentials; the latter, in some instances, approaching the appearance of single-fiber potentials. Polyphasic motor-unit potentials were increased in number. The motor-unit action potentials in myositis were similar to those found in progressive muscular dystrophy and to those produced by the injection of curare in normal muscle. Average values for motor-unit potentials of muscle biceps brachii in myositis were: amplitude, 198 ± 14 μV ($n = 137$), total duration, 5.7 ± 0.3 msec ($n = 136$), spike duration, 2.1 ± 0.09 msec ($n = 108$), negative phase, 1.4 ± 0.06 msec ($n = 106$). Comparable values in normal biceps were: 507 ± 15 μV , 8.4 ± 0.2 msec, 3.4 ± 0.07 msec and 2.2 ± 0.05 msec, respectively ($n = 180$). In contrast, values in lower motor neuron disease were: 2011 ± 218 μV , 12.9 ± 0.5 msec, 4.6 ± 0.25 msec and 2.8 ± 0.14 msec, respectively ($n = 58$). The electro-

myograms indicate that in myositis disintegration of motor units occurs by successive loss of muscle fibers from the unit. The occurrence of single-fiber potentials at rest, together with biopsy studies, suggests that this occurs by derangement of nerve terminals or motor end-plates. Degeneration of muscle fibers may also occur, but nerve trunks are intact.

Effects of inhalation of oxygen at high partial pressures upon arterial and internal jugular blood gas content, tension and pH. C. J. LAMBERTSEN, G. L. ENMEL, D. Y. COOPER, H. H. LOESCHKE and R. H. KOLGH (introduced by A. N. RICHARDS) *Lab. of Pharmacology, Univ. of Pennsylvania, Philadelphia.*

In studies of the effects upon man of inhalation of oxygen at high partial pressure (OHPP) samples of arterial and internal jugular blood were collected during control periods of air breathing at sea level and from the same subjects during oxygen inhalation at an ambient pressure of 3.5 atmospheres. Several subjects developed convulsive seizures due to toxicity of oxygen at the high arterial pO_2 produced. The table presents average results of measurements on 10 normal men, expressed in conventional units.

BLOOD MEASUREMENTS	AIR, SEA LEVEL		O_2 , 3.5 A°	
	Art.	Ven.	Art.	Ven.
O_2 content	18.6	12.3	25.8	17.7
% Hb sat	96.3	64.0	100	89.7
pO_2		37	2350	74
CO_2 content	50.2	56.1	47.3	55.4
pCO_2	44	56	40	59
pH	7.38	7.32	7.41	7.28

At 3.5 atmospheres the arterial plasma oxygen content of 6.5 volumes % nearly met cerebral metabolic requirements, as indicated by the near-arterial level of jugular hemoglobin saturation. OHPP produced a decrease of arterial and increase of jugular pCO_2 . The former suggests a moderate increase in pulmonary ventilation which was observed but not routinely measured. It is not possible to state whether these findings were related to pulmonary irritation or to central effects of CO_2 retention. Alteration of internal jugular pCO_2 and pH by OHPP are probably not important factors in development of oxygen convulsions.

Fragmentation of biliary calculi by ultrasound. HAROLD LAMPORT, HERBERT F. NEWMAN* and RALPH D. EICHORN* *Lab. of Physiology, Yale Univ. School of Medicine, New Haven Conn., and Beth Israel Hospital, New York City.*

Many types of human biliary calculi, whether

fresh or dried, were fragmented when placed in water in cellophane bags and exposed to a strong 400-kilocycle ultrasonic beam from a Crystal Research Laboratory generator in an oil bath for 5-60 seconds. Because of the change in acoustic impedance at the oil-tissue interface, the ultrasound was attenuated and excessive heat and destruction of tissue resulted when skin or fluid-filled intestine were placed in the oil ultrasonic beam. Even though the beam was attenuated on passing into water, its subsequent tissue-heating effects ceased to be serious, as measured by the appearance of tissue immediately after 15 seconds of irradiation, although longer periods still can damage tissue. Since the gall bladders of the easily available laboratory animals are not large enough, the small intestine and appendix of the rabbit have been studied preliminarily. Approximately 80% of biliary calculi placed in exteriorized loops of intestine filled with saline, but with blood supply intact, were fragmented during exposures of 10 seconds. No immediate change in the gut appeared. The later results of exposure of intestine and gall bladder to calculus fragmenting intensities of ultrasound have not yet been determined. The superior efficiency of the strong ultrasonic oil-propagated beam on the cellophane-encased stones as compared to that of the attenuated beam propagated in water suggests that a short exposure to a more intense ultrasonic beam may fragment biliary and perhaps other calculi without damage to surrounding tissue.

Effects of hypophysectomy on the respiration and cellular components of rat bone marrow DAVID LANDAU* AND ALBERT S. GORDON *Dept of Biology, Washington Square College of Arts and Science, New York Univ., New York City*

Male hypophysectomized rats (24-4 months post-operative) and intact littermate controls of the Sprague-Dawley-Holzman strain were used. The marrow cells were suspended in partially neutralized serum from animals of the same endocrine status and the cu mm O_2 consumed/mg tissue nitrogen/hour determined by the standard Warburg technique. The percentages of mature erythrocytes and nucleated cells as well as the distribution of cell types in the latter group were determined from marrow smears of the suspensions. The QO_2 (N) for the bone marrow of hypophysectomized rats— 39.2 ± 0.6 (S.E.)—was not significantly different from that of the controls— 41.3 ± 1.5 . The mean nucleated cell content of the normal rat marrow suspensions was 58.6% as compared to 69.3% in hypophysectomized rat marrow. Since mature erythrocytes have an extremely low O_2 uptake, recalculation was made of the respiratory metabolism in terms of the percentage of nucleated cellular elements. On this basis, the QO_2 (N) of the

marrow of hypophysectomized rats is found to be 19% lower than that of normal rat marrow. Hypophysectomy did not result in any alteration of the concentration of nucleated erythroid cells but did induce an increase of lymphocytes and a decrease in the numbers of immature neutrophilic myelocytes within the marrow. Preliminary experiments indicate that the bone marrows of hypophysectomized rats injected with purified growth hormone show a significantly higher QO_2 .

Chronic studies of effect of hydroquinone on man S. LANG,* N. R. BREWER AND A. J. CARLSON *Physiology Lab., Univ. of Chicago, Chicago, Ill.*

As was previously reported to the Society in April 1949, hydroquinone added to food fats in the amount of 0.01% decreases the rate of oxidative rancidity from 2 to 50 times. To further study the effects of hydroquinone 19 adult human subjects volunteered to participate in series of experiments. Two males ingested 500 mg of hydroquinone/day for 5 months after an initial control period of one month. Eleven subjects, male and female, ingested 300 mg of hydroquinone/day for 5 months after an initial control period of one month. Five males and one female ingested 300 mg of hydroquinone/day for 3 months. Thus our subjects ingested amounts approximately equivalent to a) a 30-year supply of hydroquinone in 5 months, b) a 16-year supply in 5 months, and c) a 10-year supply in 3 months, assuming that a 70 kilogram man was to ingest 1 gram of fat/kg/day and all of the fat was treated with 0.01% hydroquinone. Periodic blood and urine analysis were made throughout the duration of the experiments. Analysis of blood included percentage hemoglobin, red blood cell count or hematocrit, differential white blood count, sedimentation rate, platelet count, coagulation time and icteric index. Analysis of urine included albumen, reducing sugars, white blood cells, red blood cells, casts and urobilinogen. None of the subjects showed any symptomatology of toxicity during the course of experiments and in no case were the analyzed data significantly deviant from accepted human norms.

Bladder function following acute denervation and in spinal shock L. L. LANGLEY AND J. A. WHITESIDE (introduced by JOHN M. BRUHN) *Dept of Physiology, Med. College of Alabama, Birmingham*

The urinary bladder adapts to varying volumes maintaining a low, approximately constant pressure. Whether this is an inherent ability of the bladder musculature or is due to reflex action has been questioned. In experiments on more than 20 dogs we find that the bladder retains its capacity to accommodate to changing internal volume following complete denervation, during spinal shock at which time the micturition reflex is ab-

sent, as well as following Etamon (tetraethylammonium chloride) administration in sufficient doses to block micturition. We conclude that this phenomenon is an inherent property of the bladder musculature. Ten cc of saline introduced rapidly into the normal bladder causes an increase in pressure of approximately 3 cm H₂O. If the pelvic nerves are cut the average increase upon the introduction of 10 cc saline is 6-7 cm. This sharp rise is due to a marked increase in the tonus of the bladder wall. Severing the hypogastric nerves results in no marked or consistent change when they are cut either before or after the pelvic nerves are cut. Following complete section of the spinal cord at T₄ the micturition reflex cannot be elicited. During this period of spinal shock 10 cc saline increases the pressure only 1-2 cm, that is, the bladder is atonic. However, if the pelvic nerves are now cut, or if Etamon is given the bladder becomes hypertonic. Loss of the bladder's ability to accommodate to varying volumes is seen in spinal shock only if the bladder has previously been over-distended.

Do anesthetics depress nerve cells by depressing oxygen consumption? MARTIN G. LARRABEE, JUAN GARCIA RAMOS* AND EDITH BULBRING*
Dept of Biophysics, Johns Hopkins Univ Baltimore, Md

Effects of anesthetics or neuronal metabolism and synaptic transmission were compared by simultaneous measurements of oxygen consumption and transmission in excised superior cervical sympathetic ganglia of rabbits. A ganglion was placed in flowing solution in a small chamber in which oxygen concentration was measured with a polarized platinum electrode. Rate of oxygen consumption was determined by measuring the rate of fall of oxygen concentration when the flow of solution was stopped. Transmission was measured by height of postganglionic action potential evoked by preganglionic nerve stimulation. All anesthetics tested except urethane (chlorotone, Nembutal, ether, chloroform, also alcohols from methanol to octanol) depressed synaptic transmission reversibly without slowing the resting oxygen consumption. Urethane reversibly slowed oxygen consumption by a small amount which did not seem to increase significantly as the concentration rose from levels sparing to those blocking transmission. All anesthetics slowed resting oxygen consumption markedly at sufficient concentrations. When oxygen consumption was depressed by Nembutal or chlorotone, it could be restored by methylene blue, but depressed transmission could not. The extra oxygen consumption caused by repetitive activity was readily depressed by anesthetics, but only in direct proportion to depression of activity. In contrast with anesthetics, azide and cyanide reduced the resting

rate of oxygen consumption considerably, before depressing transmission. Cyanide depressed the extra oxygen consumption of activity more than the activity itself. These facts suggest that anesthetics depress neurones by some mechanism which does not interfere with oxygen consumption. Further interpretations are assisted by observations on sympathetic nerve trunks.

Constancy of responses to intra-arterial injection of mecholyl in isolated blood-perfused extremity. perfusion with pump-oxygenator system. BEN J. LAWRENCE, JR,* ADAM B. DENISON, JR,* J. MAXWELL LITTLE AND HAROLD D. GREEN
Dept of Physiology and Pharmacology, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem, N C

Fluctuations in blood flow in an isolated extremity perfused by an animal are due in part to a constrictor produced by the animal (GREEN, *et al Federation Proc* 1950). To eliminate such humoral factors we substituted a constant pressure pump and an oxygenator composed of glass beads for the animal. In this preparation flow was initially 10-20 cc/min/100 gm, it dropped to 2-4 cc during the first 2 hours, rose almost to the initial level at 3-4 hours then decreased practically to zero at 6-8 hours. The percentile responses to intra-arterial mecholyl varied inversely with the flow except during the terminal drop when they decreased progressively. Edema, as evidenced by leg weight gain, appeared early and increased rapidly during the terminal decline in flow but the resulting increase in viscosity was insufficient to account for the reduction in flow. Addition of chloromycetin, aureomycin or streptomycin, which prevented bacterial contamination, prolonged the experiments to 18-24 hours without materially affecting the sequence of flow changes or edema formation. Tetraethylammonium administered to leg and blood donor dogs, addition of the B complex vitamins to the perfusion system, regulation of blood pH, and, preliminary deplatelization of the blood by centrifugation at 3200 rpm for 15 minutes, to one hour were all without significant effect. Storage of pooled blood for 3-5 days at 9°C with daily addition of heparin and streptomycin minimized the fluctuations in flow.

Influence of dietary protein or thyroglobulin on liver and plasma protein levels of thiouracil-fed rats. J. H. LEATHEM
Bureau of Biological Research and Dept of Zoology, Rutgers Univ, New Brunswick, N J

Adult male rats were fed either 78% or 18% casein diets with or without thiouracil (0.5%) for 20 days. Liver protein was greatest following thiouracil and 78% casein but was significantly increased and to the same extent by 78% casein alone and by 18% casein plus thiouracil. Liver

weight, however, was only markedly increased by thiouracil. Liver water content was unchanged. Thiouracil feeding increases total plasma protein levels due to an increase in plasma globulin in addition to its effect on the liver. When adult male rats were fed thiouracil (0.25 per cent), thyroglobulin (0.05 per cent) (Prolid) or both for 20 days the plasma and liver protein effects of thiouracil were abolished. Thyroid, pituitary and liver weight increases induced by the goiterogen were counteracted by thyroglobulin whereas the cardiac hypertrophy induced by thyroid was antagonized by thiouracil.

Conversion of acetate and lactate to succinate in the intact mammal JUI SHUAN LEE* AND NATHAN LIFSON Dept of Physiology, Univ of Minnesota Med School, Minneapolis

After the administration of $\text{CH}_3\text{C}^{13}\text{OOH}$ plus normal malonate to fasted rats, $\text{C}^{13}\text{OOHCH}_2\text{CH}_2\text{C}^{13}\text{OOH}$ was recovered from the urine (LEE AND LIFSON, *Proc Soc Exper Biol & Med* 70:728, 1949). Similar studies have been made of the conversion of the following labeled compounds to succinate: $\text{NaHC}^{13}\text{O}_3$, $\text{C}^{13}\text{H}_3\text{C}^{13}\text{OOH}$, $\text{CH}_3\text{CHOHC}^{13}\text{OOH}$, $\text{C}^{13}\text{H}_3\text{C}^{13}\text{HOHCOOH}$. The results may be summarized as follows: 1) $\text{NaHC}^{13}\text{O}_3 \rightarrow \text{C}^{13}\text{OOHCH}_2\text{CH}_2\text{C}^{13}\text{OOH}$, 2) $\text{CH}_3\text{C}^{13}\text{OOH} \rightarrow \text{C}^{13}\text{OOHCH}_2\text{CH}_2\text{C}^{13}\text{OOH}$, 3) $\text{C}^{13}\text{H}_3\text{C}^{13}\text{OOH} \rightarrow \text{C}^{13}\text{OOHC}^{13}\text{H}_2\text{C}^{13}\text{H}_2\text{C}^{13}\text{OOH}$, 4) $\text{CH}_3\text{CHOHC}^{13}\text{OOH} \rightarrow \text{COOHCH}_2\text{CH}_2\text{COOH}$, 5) $\text{C}^{13}\text{H}_3\text{C}^{13}\text{HOHCOOH} \rightarrow \text{C}^{13}\text{OOHC}^{13}\text{H}_2\text{C}^{13}\text{H}_2\text{C}^{13}\text{OOH}$. In the case of result (1), the concentration of labeled carbon was of borderline significance only. These isotope distribution patterns in the urinary succinate are consistent with the *in vivo* operation of the tricarboxylic acid cycle as influenced by malonate inhibition of the conversion of fumarate to succinate.

Nutritional and metabolic factors in peripheral vasomotor reactions: vasocompensatory impairment induced by avitaminosis C RICHARD E LEE (introduced by B W ZWEIFACH) Dept of Medicine, Cornell Univ Med College and The New York Hospital, New York City

As compared to 12 pair-fed controls and an adequately supplemented synthetic diet, 11 guinea pigs deficient in vitamin C for 21-23 days show no demonstrable differences in blood pressure or in their ability to respond in pressor manner to intravenous and intra-arterial injections of epinephrine. However, when subjected to standardized graded hemorrhage, in contrast to the animals on a fully supplemented diet, the vitamin-C-deficient animals were consistently incapable of elaborating the renal humoral vasoconstrictor material, VEM. Tests were carried out on the unfractionated plasma using the rat mesoappendix method. In addition, these animals were much less resistant

to hemorrhage than their pair-fed controls. The amount of blood loss necessary to reduce the blood pressure to $\frac{1}{3}$ its initial value was approximately 50% of that of the controls. The removal of an additional cc of blood, which was well tolerated by the supplemented animals, was followed by a gradual fall of blood pressure to zero in 8 of the ascorbic-acid-deficient animals.

Effects of the shear bacterial polysaccharides upon cardio-vascular response CHESTER E LEESE, WILLIAM E POEL* AND HAROLD BERMAN* Dept of Physiology, George Washington University Med School, Washington, D C

Rabbits were given doses of polysaccharide from 100 to 1200 gamma/kg. This substance has been shown to be effective in destroying cancer tissue, but possesses strong toxic properties. Electrocardiograms showed tachycardia as the most persistent finding with inversion of the P and T waves, and abnormally high S-T takeoffs. All irregularities were reversible and disappeared within 6 hours after intravenous administration. Blood pressure dropped within 10 to 40 seconds after polysaccharide administration, and was maintained at $\frac{1}{3}$ to $\frac{1}{2}$ of its original level for 5 to 10 minutes. A gradual return to normal limits was then observed, which required 15 to 40 minutes. Following recovery of the pressure level, injections of the agent had no appreciable effect. It appears that the depressor action may be tachyphylactic in nature. Histamine was suggested as the depressor agent because of the destructive power of the polysaccharide upon cancer cells. Antihistamine drugs did not prevent the depressor response. Circulation time was increased in response to polysaccharides, measured by the cyanide method. The recommended dose of cyanide proved fatal in several instances following polysaccharide, but was never fatal to the controls.

Degradation of fatty acids to 'acetate' by neurospora JOSEPH LEIN AND PATRICIA S LEIN (introduced by W W SWINGLE) Dept of Zoology, Syracuse Univ, Syracuse, N Y

A mutant of *Neurospora crassa*, S210, which grew in minimal medium supplemented with oleic acid was isolated. Further study showed that the mutant did not grow when supplemented with amino acids or water-soluble vitamins but did grow well in acetic acid. Growth of the mutant in acetic acid could be very markedly inhibited by arginine or lysine but not by other amino acids. Experiments were carried out in which oleic acid or acetic acid was used as the sole carbon source, and it was found that the mutant could derive its carbon as well as its necessary supplement from both acids. This result was thought to indicate that the mutant was actually an acetate mutant and that its acetate could be derived from

oleic acid The possibility also exists that acetate itself is not the fragment formed from the fatty acid but rather that a compound closely related to it may be the one produced *in vivo* With this reservation in mind, naturally occurring fatty acids were tested to see if they could serve as 'acetate' donors for the mutant The compounds were tested for inhibition effects using wild type so that inhibition phenomena would not mask their ability to enable the mutant to grow From the growth studies it appeared that *Neurospora crassa* can degrade butyric, caproic, caprylic, capric, lauric, myristic, oleic, linoleic and linolenic acids into 'acetate' enabling the acetate mutant to grow Stearic and palmitic acids were not degraded to usable 'acetate' compounds

Positivity in ventral horn during bulbar reticular inhibition of motoneurons JEROME Y LETTVIN AND PAUL C DELL (introduced by WARREN S McCULLOCH) *Manteno State Hospital and Dept of Psychiatry, Univ of Illinois College of Medicine, Chicago*

We have previously shown that the suppressor bulbar reticular fibres in the ventrolateral fasciculus terminate in the internuncial nucleus of the Lateral Column of Ramon y Cajal (the Tractus Cellularum Intercornualis Lateralis of Jacobsohn) and that stimulation here inhibits and only inhibits the motoneurons even when the current is strong enough to excite initially the motoneurons themselves We now show that this inhibition is accompanied by a long positive potential in the motoneuron pool resembling the positive 'synaptic potential' recorded by Eccles with intersegmental reflex inhibition

Effect of insulin on transport of certain substances across cell barriers R LEVINE, M S GOLDSTEIN* AND B HUDDLESTON* *Dept of Metabolic and Endocrine Research, Med Research Inst, Michael Reese Hospital, Chicago, Ill*

The intimate mechanism by which insulin acts has been looked for in a 'biocatalytic' effect on one or several of the enzymatic steps of the intermediary metabolism of glucose However, insulin may not exert any direct action whatever upon the known enzyme systems of the accepted carbohydrate scheme, but it may act by promoting the rate of transfer of glucose (and perhaps other substances) across certain cell membranes Accordingly we are investigating the effect of insulin upon the rate of entry into tissues of substances other than glucose, preferably non-utilizable, organic, naturally occurring compounds We have recently reported that insulin increases the rate and extent to which galactose is distributed in the tissues of eviscerated nephrectomized dogs (*J Biol Chem* 179: 985, 1949) On the basis of existing evidence it was then assumed that the administered galactose was not 'utilized' (transformed in any way) This

has now been experimentally demonstrated The above experiments were repeated using eviscerated nephrectomized rats and analyzing the whole carcass Our data show that at the end of the experimental period none of the administered galactose has disappeared as a result of insulin administration It can be concluded, therefore, that insulin is affecting some 'permeability' process by which galactose gains entrance into cells Preliminary experiments indicate that this type of insulin effect can also be obtained by using fructose and lactate but that insulin does not affect the distribution of urea, creatinine or sucrose

Quantitative determination of fluorescein passage through capillaries following ultraviolet irradiation of transparent rabbit ear chambers EDWARD A LICHTER* AND ALFRED A SCHILLER *Dept of Physiology, Univ of Illinois College of Medicine, Chicago*

Modified transparent chambers, similar to those described by Ebert, have been inserted in rabbit ears to study the manner in which fluorescein dye injected *iv* enters and leaves the tissue spaces under various dosage levels of ultraviolet irradiation calculated to affect changes in capillary permeability The radiation was directed through the polished quartz table of the chamber in dosage levels approximating rabbit belly threshold erythral responses Alterations in the size of the vascular bed were determined from serial photomicrographs taken during the control and experimental periods Approximately 4-5 hours after ultraviolet irradiation of the chamber, 50 mg/kg of Na fluorescein in 5 % solution was injected intravenously followed by measurements of the intensity of fluorescein fluorescence in a given microscopic field in the chamber at 1- to 2-minute intervals for a period of 60-90 minutes Fluorescence was determined photometrically by a sensitive, suitably filtered, multiplier photocell adapted to the microscope ocular The photocell was standardized against a piece of stable fluorescent glass placed on the microscope stage above a constant intensity lamp The arithmetically integrated areas delimited by the time-intensity (fluorescence) curves provide indices of comparison between control and irradiation conditions In several animals under comparable experimental conditions, it was observed that the rate and peak intensity of dye transudation and resorption was greater following irradiation, each chamber serving as its own control Characteristic deviations of the experimental chamber from the control, during 3 successive 20-minute intervals, were a) 103 % increase in dye, b) 11 % decrease, and c) 27 % decrease, respectively

Non-chronotropic T-wave changes produced by acetylcholine IRVING M LIEBOW AND HERMAN

K HELLERSTEIN (introduced by VICTOR LORBER) *Dept of Medicine, School of Medicine, Western Reserve Univ, Univ Hospitals, Cleveland, Ohio*

The effects of acetylcholine upon the blood pressure and upon intracavitary and extracavitary leads of the electrocardiogram of the intact nembutalized dog were studied. Acetylcholine in amounts from 0.01 microgram to milligrams was injected into the right atrium and mid abdominal aorta via indwelling catheters. 1) Intra-atrial and intra-aortic doses as small as 0.01 μ g produced a significant fall in blood pressure. The former route produced changes in the electrocardiogram. Acetylcholine therefore is effective in minute doses in the intact anesthetized animal. 2) PTA depression and increase in the amplitude of the T wave (extracavitary leads) were found to be early and independent of the blood pressure changes. PTA depression occurred in 31 of 34 experiments before blood pressure fall and in the absence of chronotropic effect. The same was true of T wave changes in 9 of 31 experiments. The changes are considered to be a direct effect of acetylcholine. 3) Acetylcholine produced greater negativity of the intracavitary T wave and greater positivity of the extracavitary T wave. On the basis of current concepts, acetylcholine either hastens repolarization of the ventricular sub-epicardial lamina or retards it in the sub-endocardial lamina.

Electro-icongo-grams from the cerebral cortex (cats) at the pial surface 'spontaneous' activity and responses to endorgan stimuli under anesthesia JOHN C LILLY AND WILLIAM W CHAMBERS (introduced by H C BAZETT) *E R Johnson Fdn for Med Physics, Univ of Pennsylvania, Philadelphia*

A new technique and some of the results of its use are described briefly. The Bevatron (A I E E - I R E Symposium Volume on Instrumentation in Medicine and Nucleonics, to be published by the American Institute of Electrical Engineers in 1950) records some 2 dimensional cross sections of the 3-dimensional electrical activity of the brain (electro-icongo-grams). The input field is picked up by 25 electrodes in a 5 x 5 square array (8 mm by 8 mm) on the pia, is amplified by 25 amplifiers, and used to intensity-modulate 25 light sources in a 5 x 5 square array at the output. The moving and fixed figures and forms of the electrical input field are thus transformed into corresponding patterns of variation of luminosity of the output field. The output field is photographed with a motion picture camera at 128 frames/sec to obtain the records called electro-icongo-grams or E I G.s. By projecting the E I G.s at 16 frames/sec on a screen subtending a visual angle of 0.1° to 1.0°, the following results can be seen by the observer. 1) In deep barbiturate anesthesia, the cortical responses to nor-

mal endorgan stimuli can be seen to spread in the primary afferent areas in a stereotyped fashion from the zone first activated. 2) 'Barbiturate waves' are seen to be simple forms which travel or which 'grow' around a focus and fade away in place. 3) Spontaneous activity in the conscious animal has traveling, shifting figures of various velocities, sizes, and forms, depending, grossly, on previous stimuli.

Behavioral and EEG changes following chronic brain stem lesions D B LINDSLEY, L H SCHREINER,* W B KNOWLES* AND H W MAGOUN *Depts of Anatomy and Psychology, Northwestern Univ, Evanston, Ill*

The possibility that wakefulness and EEG desynchronization, in the arousal reaction to afferent stimuli, might depend upon an ascending influence of the brain stem reticular formation, rather than upon the influence of afferent volleys arriving at the cortex over classical sensory paths, was explored by observing the behavior and EEG's of cats with large, chronic lesions of the midbrain or diencephalon. After destruction of the anterior midbrain tegmentum or hypothalamus, sparing sensory connections to thalamus and cortex, the animals usually appeared asleep. Their EEG's exhibited slow waves and spindle bursts. Ordinary stimulation was ineffective, but stronger auditory or nociceptive stimuli evoked motor responses and EEG desynchronization. Arousal was brief, usually not outlasting stimulation. After mesencephalic interruption of the medial and lateral lemnisci and spinothalamic tracts, the animals were not abnormally sleepy and showed waking EEG's. When relaxation or sleep occurred, arousal and EEG activation was readily induced by afferent stimuli and usually persisted for long periods after stimulation. Of these two systems influencing the cortex, that through the tegmentum and hypothalamus thus appears of greater importance in maintaining wakefulness and inducing EEG arousal upon afferent stimulation. However, after large rostral tegmental or hypothalamic lesions, afferent stimuli are still able both to arouse the animal and activate its EEG. These effects seem attributable either to the direct influence of afferent volleys upon the cortex, or to collateral excitation of diffuse projection nuclei at the thalamic level. The consequences of chronic thalamic lesions are under study.

Nature of muscle membrane potential GILBERT LING (introduced by R W GERARD) *Dept of Physiology, Univ of Chicago, Chicago, Ill*

Earlier work led to the view that the membrane potential (MP) of skeletal muscle fibers (single unpaired frog sartorius fibers) is of the Donnan type and varies with metabolic and other conditions as the balance of permeable and imperme-

able ions is altered. Thus the A potential (55-80 mV) was shown to depend on impermeable CrP and to fall in proportion as this splits to permeable PO_4 and Cr. The B potential (0-55 mV), less metabolism sensitive, has been related to other ions, especially carnosine and hexose phosphates. If hexose 6 P is increased by soaking in adrenaline, the B potential is proportionally increased. The late rise of B potential, previously found under IAA action, has similarly been shown to parallel a rise in hexose phosphates. It is also associated with a rise of internal cations, not of K at this stage (though some bound K may become free) but of NH_4 , released from split ATP, and probably others. Such appearance of extra ions inside reflects itself in an increase in osmotic pressure, and in fact muscle weight increases in strict parallelism with the B potential. The normal MP should equal $\frac{RT}{F} \ln \frac{K_i}{K_o}$ and also equal $\frac{RT}{F} \ln \frac{(R_i)}{(K_o)}$

+ $\frac{(\text{Na}_o)}{(R_i)}$, where (R_i) is the total inside concentration of impermeable anions. From the known or directly measured values in these equations, the MP calculates, respectively, to 105 and 100 mV. The directly measured MP (corrected for junction potential) is 97.6 ± 5.7 mV, maximum 110. Under non-equilibrium conditions, as in IAA poisoned muscle, when NH_4 is being produced at the same time as K^+ is leaking out, the more complete equation of Hodgkin and Katz (*J Physiol* 108: 37, 1949) is preferable, as the inside-outside ratios of different permeable ions are temporarily unequal.

Role of changes in metabolism in acclimatization of albino rats to reduced barometric pressure

JEROME L. LIPIN* AND WILLIAM V. WHITEHORN
Dept. of Physiology, Univ. of Illinois College of Medicine, Chicago

Re-investigation of possible reduction in metabolism in acclimatization to oxygen lack was suggested by reports of such decrease in congenital heart disease. Twenty-four 170 gm male albino rats were acclimatized to 18,000 feet simulated altitude by exposure for 30 days, the final pressure being attained gradually over a one-week period. Maintenance of growth and increase in hemoglobin indicated true acclimatization. O_2 consumption was measured by an open circuit method with specially designed mask and valve system. Metabolism of experimental animals declined 32.7, 38.5 and 40.5% from control values after 0, 2, and 4 weeks at reduced pressure, respectively, and remained at -38.5 and -36.8% for 2 weeks following return to ground level pressures. Values for littermate controls at ground level pressures declined 23.1, 23.1, 32.7, 38.5 and 34.6% on corresponding dates. Decreases from control levels are statistically significant in both experimental and control

groups but not between these groups, and are probably due to factors of training and increasing age of animals. These data on growing rats thus support the concept that reduction in total O_2 consumption plays no role in acclimatization to anoxia and raise a question as to the presence of true acclimatization in congenital heart disease.

Effect of egg white injections upon excretion of hemoglobin in the rat

RICHARD W. LIPPMAN AND HELEN J. URFEN (introduced by HARRY GOLDBLATT)
Inst. for Med. Research, Cedars of Lebanon Hospital, Los Angeles, Calif.

We have previously reported that when hemoglobin is administered intravenously, after the production of proteinuria by intraperitoneally administered bovine albumin, there is a sharp increase in the rate of hemoglobin excretion and a pronounced depression of the threshold serum hemoglobin concentration, when compared with control animals that have received intraperitoneal saline solution. In current experiments we have investigated the effect upon hemoglobin excretion of intraperitoneally administered crude egg white, with concomitant proteinuria. Experiments were made according to the plan of previous work. Rats received 3 injections of saline solution intraperitoneally, the second injection containing 1 gm crude egg white. Hemoglobin was administered intravenously after subsidence of the edema and vascular disturbance that follows egg white administration, but during maximal proteinuria. It was found that, under these conditions, the threshold serum hemoglobin concentration is slightly increased, but the rate of excretion at higher concentrations is slightly diminished. Creatinine clearances were determined simultaneously and, when corrections for the change in glomerular filtration rate are introduced, it appears that egg white reduced the tubular reabsorption of hemoglobin but did not significantly affect glomerular permeability to hemoglobin. This is in contrast to the effect of bovine albumin, which reduced tubular reabsorption of hemoglobin but which sharply increased glomerular permeability to hemoglobin.

Effect of renin upon excretion of hemoglobin in the rat

RICHARD W. LIPPMAN AND HELEN J. UREEN (introduced by HARRY GOLDBLATT)
Inst. for Med. Research, Cedars of Lebanon Hospital, Los Angeles, Calif.

By the technique previously reported, the effect of intravenous renin administration upon the excretion of intravenously administered hemoglobin was studied in the rat. Animals were given 3 intraperitoneal injections of saline solution, succeeded by intravenous administration of hemoglobin solution containing 4 Goldblatt dog units of renin. Control animals received similar injections, except for omission of the renin. Simultaneous cre-

atimine clearances were performed. When correction was made for the slight fall in glomerular filtration rate which accompanied renin administration, it was seen that there had been a sharp increase in the rate of hemoglobin excretion, when compared with control animals at comparable serum concentrations. This is considered to indicate a pronounced increase in the glomerular permeability to hemoglobin under the influence of renin. Preliminary results indicate that the tubular reabsorption of hemoglobin, after renin administration, is significantly increased.

Serial determinations of morning gastric secretion in patients with peptic ulcer A. LITTMAN,* C. E. ROSIERE* AND A. C. IVY, *Dept. of Clinical Science, Univ. of Illinois College of Medicine, Chicago*

At intervals, usually of 2 to 4 months, we aspirated the fasting unstimulated morning gastric secretion for 90 minutes in 16 ambulatory patients with duodenal ulcer. These studies were carried out for 1- to 3-year periods to determine the possible relationships of the acid and volume output to the patients' clinical courses, treatment and other variables. In 8 cases there were sharp drops in hourly acid output after the first tests, these patients all had typical ulcer symptoms at the time of the first test. However 5 of the 8 patients failing to manifest such a drop with remission also had active symptoms. Of 9 cases in which tests were done during subsequent recurrences, in 8 there were no accompanying rises in acid output, indicating that morning gastric secretion was not influenced by 'activity' of the ulcer. However, all recurrences under observation were of brief duration prior to testing, while the episodes present at the time of the first tests were sometimes protracted and severe, suggesting that sharp falls from initially high levels in the first tests occurred most often in association with remission from prolonged and severe clinical episodes. In only a few instances was there a possibility that antacid therapy was related to fluctuations in acid output. Also, treatment with atropine in 3 of 7 cases resulted in pronounced diminution of acid secretion although medications were always withheld for 36 hours before each test. Stopping atropine in these three cases was followed by sharp rises in acid output.

Gastric secretory inhibitor factor in canine gastric juice GEORGE R. LIVERMORE, JR.* AND CHARLES F. CODE, *Section on Physiology, Mayo Clinic and Mayo Fdn., Rochester, Minn.*

Gastric juice was collected from Heidenhain and Pavlov types of gastric pouches while these were secreting in response to subcutaneous injections of mecholyl or histamine. After neutralization, a

fraction of the juice was precipitated by the addition of ethanol until the concentration of ethanol in the sample was 80%. The gastric secretory inhibitor activity of this precipitate after it had been dissolved or suspended in physiologic saline solution was determined by the assay procedure of Code, Blackburn, Livermore and Ratke (*Gastroenterology* Dec., 1949). In most instances the intravenous injection of the precipitates inhibited gastric secretion. The inhibitor factor was most concentrated in juice from Pavlov pouches after stimulation with mecholyl and least in juice from Heidenhain pouches after stimulation with histamine. A higher concentration of the active material was present in juice from a Heidenhain pouch after stimulation with mecholyl than in juice from a Pavlov pouch after stimulation with histamine but the inhibition produced by equal weights of the 2 types of precipitates was slightly greater in the case of the juice from a Pavlov pouch after injection of histamine. Changes in body temperatures during the assays were recorded and the correlation between these and the amount of inhibition has been studied. It was found that in many cases a correlation did exist between body temperature and inhibition but in addition it was noted that a high degree of inhibition sometimes occurred without fever and conversely a high fever was sometimes present without significant gastric secretory inhibition.

Establishment and relief of asphyxial blocks in spinal motoneurons DAVID P. C. LLOYD, *Labs. of Rockefeller Inst. for Med. Research, New York City*

An exploring electrode may be so placed on, or in, the cord that antidromic responses of intramedullary myelinated axons (M-segment), initial axonal segments (I-segment), bodies, and dendrites of motoneurons are distinguishable. Interpretation of asphyxial changes in these responses is facilitated by observations on cocaine block of nerves in volume conductors. Below a block normally triphasic, responses become monophasic positive deflections. Above a developing block, the 2nd (negative) phase increases *pari passu* with loss of the 3rd phase, demonstrating that intensity of the sink at a point increases when that point does not subsequently become a source for sinks developing beyond that point. Thus, in volume, blocks are located between points at which negative phases increase and points at which negative phases disappear. On asphyxia M-segment responses, normal for some 3 minutes, increase rapidly to a maintained maximum, while all other responses disappear. Promptly, on restoring ventilation, M-segment responses decrease precipitately, but incompletely, I-segment responses re-

cover and overshoot, while dendritic responses remain absent. Then, slowly, as dendritic responses recover, M segment responses further decrease, and I segment responses decline from overshoot level toward normal. Therefore, asphyxial block, established between axon segments, on reventilation shifts toward the dendrites before resolving. After repeated asphyxial insult, blocking time increases and, coincidentally, the influence of asphyxial hyperexcitability becomes apparent as a transient augmentation, before block is reestablished, of response in depressed dendrites. Asphyxial changes in dendritic response now resemble somewhat those, described by Brooks and Eccles, in the 'antidromic focal potential' of spinal cords depressed by sodium pentobarbital (Nembutal).

Sodium as inhibitor of potassium effect upon frog nerve fibers ANDERS LUNDBERG (introduced by R. LORENTE DE NÓ) *Rochefeller Inst for Med Research, New York City*

Treatment of frog nerve (spinal roots or sciatic nerve trunk) with sodium chloride at 2-3 times the concentration present in Ringer's solution (0.1N) results only in a slight depolarization of the nerve fibers, nevertheless, the presence of an excess of sodium ions in the external fluid of the nerve fibers markedly inhibits the depolarizing action of a given excess of potassium ions, insofar as both the rate at which the depolarization is established and the maximal depolarization itself are considerably less than when the excess of potassium ions is present in an isotonic (0.1N) solution. On the other hand, decreasing the tonicity of the solution by withdrawal of sodium chloride results in an increase in the rate of depolarization by potassium chloride (0.05N). An oscillographic analysis has been carried out of the effect of an excess of sodium ions upon the nerve fibers. Even after several hours 0.33N sodium chloride does not block conduction of impulses. The most remarkable change observed consists in a reduction in the fast electrotonus.

Circulation in membranes of the frog and hamster after stasis, trauma and under pathological conditions BRENTON R. LUTZ, GEORGE P. FULTON* AND ROBERT P. AKERS* *Dept of Biology, Boston Univ, Boston, Mass*

Blood flow in small vessels of the frog retrolingual membrane, vocal sac, bladder and mesentery, and of the hamster cheek pouch was studied for sludged blood, under normal, pathological and surgical conditions, and after stasis. Reflected and transmitted light were used with magnifications from $\times 54$ to $\times 520$. True sludged blood was not found in hamsters with advanced tumors, staphylococcus infection or surgical trauma, nor in frogs

traumatized or with 'red leg'. Apparent sludged blood occurred in some hamsters in vessels examined by reflected light at low magnifications ($\times 54$, $\times 90$). The same vessels seen by transmitted light at higher magnification ($\times 200$) showed erythrocyte groups separated by plasma, white cells and platelets. When these erythrocyte groups were compressed by a microprobe, the individual erythrocytes separated freely, and passed separately into capillaries. After stasis for days, erythrocytes packed in vessels remained unagglutinated and flowed individually when the vessel was rubbed with a microprobe or cut with a microknife. A significant result of venous occlusion, for 20-45 minutes by clamping cheek pouch vessels, was mass platelet accumulation on some vessel walls at release. Individual platelets or small groups broke off into the stream, then additional platelets collected at the same place. Frequently channeling of blood flow through complex routes in adherent platelet masses occurred, but sludged blood was not observed under these conditions. These platelet masses may be the basis of local or remote thrombus formation following injury and stasis.

Determination of amount of ice formed in blood at various freezing temperatures BASILE LUYET AND PAUL SCHMIDT* *Dept of Biology, St Louis Univ, St Louis, Mo*

Though freezing is a classical method for producing hemolysis, it has been reported that blood can be frozen solid, above -3°C , without appreciable hemolysis (STRUMIA *Conference on Blood Preservation* Harvard 1949, p. 160). It was suggested (LUYET, *ibid*, p. 144) that the erythrocytes escape congelation and injury because they become gradually dehydrated by exosmosis in the concentrated plasma left when water crystallizes out of blood in the process of freezing itself. To check this possibility we determined calorimetrically the amount of ice formed in blood exposed to temperatures from -1° to -25°C . The blood to be frozen—oxygenated ox blood—was sealed in glass ampules, and these were cooled in a mercury bath maintained at the desired temperature. The following values, taken from a curve obtained with the blood of one animal, represent the essential findings.

Temperature ($^{\circ}\text{C}$)	-2°	-4°	-6°	-8°
% of water-content frozen	75	84	84	89

The amount of ice formed did not increase further when the temperature was lowered from -8° to -25° . Thus at -2° only some $\frac{1}{4}$ of the water is frozen (59% of the entire blood, the water-content being 77.9%), this is enough to make the blood appear 'frozen hard,' but sufficient room is left in

the interstices for the partially dehydrated erythrocytes to be preserved in 'cold storage'

Resumption of rhythmic contractions by amniotic muscle after its solidification in liquid nitrogen

BASILE LUYET AND FEDERICO GONZALES * *Dept of Biology, St Louis University, St Louis, Mo*

Excised fibers of skeletal muscles were reported previously to respond to electric stimulation after they had been solidified in liquid nitrogen if the rate of cooling and rewarming was of the order of several hundred degrees/sec. The present report is concerned with the resumption of rhythmic contraction after the same treatment in a system which is spontaneously contractile, the nerve-free smooth muscle of the amnion. Pieces of amnion of the chick were partially dehydrated by immersion in a solution of ethylene glycol, then, after the excess solution was blotted off, they were dipped in liquid nitrogen, finally they were rewarmed rapidly by immersion in Tyrode solution at 40°. Rhythmic contractions were usually resumed upon contact with a glass rod and they continued spontaneously for 15-30 minutes. Some injury resulted from the low temperature treatment: contractions were often less pronounced than in the controls, the percentage of responsive strips was smaller and the survival time was shorter. The nature of the conditions permitting recovery—ultra-rapid cooling, ultra-rapid rewarming and dehydration—and dependence of the degree of injury on the non-fulfillment of these conditions, support the view that life is preserved to the extent to which crystallization is avoided.

Substitutes for procaine in ventricular tachycardia

E L McCawley, J E Stanwood* and N A David *Dept of Pharmacology, Univ of Oregon Med School, Portland, Ore*

Surgical manipulation during operations involving the great vessels (Blalock, Smithwick) and coarctation predisposes to ventricular arrhythmias especially when the most preferred anesthesia, cyclopropane, is used. While procaine hydrochloride has been found effective in preventing these arrhythmias, a large dose is required and its action is brief. We have undertaken an investigation of the possibility of using other compounds for this purpose. Using dogs, ventricular arrhythmias have been produced by cyclopropane-epinephrine and chloroform-barbiturate-epinephrine combinations and by traumatic manipulations in the thoracic and abdominal cavities during cyclopropane anesthesia. The mesenteric Pacinian corpuscles appear to be particularly involved as a source of stimulus initiating irregularities in the sensitized heart. Diphenhydramine (J M White and E L McCawley, *Abstracts, Pharmacology Soc Meeting, Indianapolis, 1949*) has proven superior to procaine in preventing the ventricular arrhythmias initiated by these various procedures. Diphenhy-

dramine has a lower minimally effective dose and a greater duration of action. If diphenhydramine solution is administered slowly, no significant hypotension occurs. While there appears to be no change in the level of anesthesia, muscular twitchings may occur. We found 'Pronestyl' (N'-(2-diethylamino ethyl)-p-aminobenzamide) also effective and to have a longer duration of action than procaine. Ventricular fibrillation occurs in one-fifth of the animals developing arrhythmias if no protective drug is administered. Procaine, diphenhydramine and Pronestyl markedly reduces this incidence. In no case, however, could ventricular fibrillation, once established, be reversed.

Location of receptors for tonic neck reflexes

G P McCouch, T H Ling,* I D Deering* and D Scott, Jr * *Depts of Physiology and Anatomy, Univ of Pennsylvania School of Medicine, Philadelphia*

In 8 decerebrate, labyrinthectomized cats, the tonic neck reflex to head turning was retained after either section of all muscles connecting head with neck and atlas with axis (4 cats), or bilateral section of muscular branches of the first 3 cervical nerves (2 cats), or section of both muscles and nerves (2 cats). In 6 decerebrate, labyrinthectomized cats the first 2 or 3 cervical nerves were exposed with as little dissection of muscle as possible. The tonic neck reflex to turning the head was clearly present. An attempt was then made to denervate the upper neck joints by circumsection of the first 2 or 3 cervical nerves at their emergence through the intervertebral ligaments without injuring muscular branches. When this was done unilaterally, the neck reflex was abolished in the ipsilateral extremities, when bilaterally, it was absent in all 4 limbs. In a few preliminary experiments designed to study the discharge of joint receptors, discharges have been recorded from atlanto-occipital and atlanto-axial ligaments and from the region of the 2nd cervical root between its emergence from the ligament and the ganglion after section of branches traversing muscle. These discharges have been elicited by flexion and extension and by rotation of the head. It is concluded that receptors for the tonic neck reflex to turning the head are located in the atlanto-axial and occiputo-atlantal joints. If there be muscular receptors which facilitate this reflex, their effect in isolation is subliminal under the conditions of these experiments.

Physiological and pharmacodynamic studies of blood from x-ray personnel

DAVID I MACHT AND STANLEY H MACHT * *Depts of Pharmacology and Radiology, Sinai Hospital, and Dept of Radiology, Baltimore City Hospitals, Baltimore, Md*

The senior author has called attention in many publications to the fact that certain seedlings grown in hydroponic plant-physiological solutions

under strictly controlled ecological conditions, are able to detect abnormal or toxic constituents in 1% solutions of blood serum, even though these are not detectable by ordinary pharmacological or biochemical methods. Thus it was shown that blood sera of various animals, including men, exposed to x-rays are definitely toxic for the growth of *Lupinus Albus* roots. In the present investigation, studies were made in two Baltimore hospitals of blood specimens taken from physicians, students, technicians, clerks and other personnel employed in their radiological departments. Phytopharmacological tests were made on the one hand and morphological examinations on the other hand. It was discovered that almost all of the blood sera from x-ray personnel possessed phytotoxic properties, even before morphological changes could be discovered in the blood smears. A considerable number of the subjects also revealed changes in the blood cells, such as leucocytosis, etc. The findings point to the fact that stray radiations do occur in x-ray laboratories in spite of all the ordinary precautions taken to keep them out. This was corroborated by tests with supersensitive films. The hygienic implications of the above findings are obvious.

Phytotoxic properties of normal and some pathological spinal fluids DAVID I. MACHT, *Dept. of Pharmacology, Sinai Hospital, Baltimore, Md.*

The author has been studying for 25 years the phytotoxic properties of normal and pathological blood sera. As a result of these studies, it was definitely established that the blood sera of a few pathological conditions produced definite phytotoxic effects, mainly inhibition of root growth of *Lupinus Albus* seedlings grown under standardized, ecological conditions in plant physiological solution (*J. Lab. & Clin. Med.* 26:597, 1941 and *Bull. Torrey Botanical Club*, 76:235, 1949). Thus, it was shown that the following conditions produced marked inhibition of root growth: cataplexy, pernicious anemia, leprosy, trachoma, pemphigus and various psychoses. More recently studies were begun on spinal fluids. It was found that a 2% solution of normal spinal fluid yields an average index of growth of 92%. Experiments with spinal fluids from menstruating women, and from patients afflicted with pernicious anemia, pemphigus, and both functional or organic psychoses all yield characteristic phytotoxic indices of growth.

Changes in vital capacity following release of tourniquets obstructing venous return I. F. S. MACKAY, *Dept. of Physiology and Pharmacology, Univ. College of the West Indies, Jamaica, B. W. I.*

It is well known that the vital capacity diminishes when the recumbent position is assumed. The mechanism responsible has been examined by Hamilton and Morgan (*Am. J. Physiol.* 99:526,

1932). These authors suggest that when a subject lies down, blood is poured from the dependent veins into the lungs. In support of this they showed that tourniquets applied to the four limbs at diastolic pressure caused an increase in vital capacity. The changes in vital capacity following the release of the tourniquets in the recumbent position form an interesting pattern. There is firstly an immediate and sharp decline in vital capacity followed by a rise and then a fall to a plateau. The technique used was that of Mackay (*J. Physiol.* 107:89, 1943).

	SUBJ. A	SUBJ. B
Recumbent vital capacity, liters		
With tourniquets	4.77	4.90
After tourniquets are released (at ½ min. intervals)		
0.5	4.55	4.62
1.0	4.66	4.62
1.5	4.62	4.72
2.0	4.58	4.68
2.5	4.51	
3.0	4.47	4.66
4.0		4.77

Cardiac acceleration to atropine cannot be conditioned THAYER M. MACKENZIE* AND W. HORSLEY GANTT, *Pavlovian Laboratory, Phipps Clinic, Johns Hopkins Univ., Baltimore, Md.*

This laboratory has been concerned with the laws governing conditional reflex (cr) formation. The criterion as to whether a reaction can be conditioned depends not upon the reaction but upon the method of its production. Previous studies from this laboratory have shown that a response involving central nervous system excitation can be conditioned, but the same response produced by peripheral stimulation can hardly be conditioned. Thus a) salivation evoked by pilocarpin, gastric secretion from histamine injection, and hyperglycemia from adrenaline injection cannot be conditioned, but b) salivation and gastric secretion as components of food reaction, and the emotional hyperglycemia are readily conditioned. In cases under a) effect is produced by action on afferent nerve endings or directly on tissues, while in b) the action is result of central nervous excitation. Similarly we have formed cardiac crs where acceleration occurs as a component of central excitation, e.g. food, pain. Atropine was injected from another room by special technique to eliminate presence of experimenter, a marked unconditional increase to atropine could not be conditioned. Using saline as a conditional stimulus and 0.1 mg/kg atropine as unconditional stimulus the results were (average of 10 experiments) Rhett atropine 93 control to 141 and saline control

116 to 106, 13th minute after injection Ehza atropine 94 control to 181 and saline 103 control to 93, 11th minute after injection The cardiac like other reactions, to be conditioned, must result from central rather than peripheral excitation

Effect of lithium on the electrocardiogram of animals VICTOR A. MCKUSICK (introduced by JAMES A. SHANNON) *Cardiovascular Clinic, U S Marine Hospital, Baltimore, Md*

Elevation of serum potassium produces a pathognomonic sequence of electrocardiographic changes in animals and in the human. This study had as its objective a definition of the electrocardiographic effects of the lithium ion. In experiments roughly parallel with those of Winkler *et al* (*Am J Physiol* 124 478, 1948) for the potassium ion, isotonic (0.65%) lithium chloride solutions were infused intravenously in 6 dogs, 1 cat and 2 rabbits. Intermittent electrocardiographic observations were made and the blood level of lithium correlated therewith. In 6 guinea pigs the lithium chloride solution was administered intraperitoneally in intermittent doses and only the lithium blood level at cardiac arrest was determined, although the full sequence of EKG changes was recorded. In all these animals a consistent series of EKG events was observed: 1) amplification of the T waves, 2) auricular standstill or fibrillation, 3) widening of the QRS complex, and 4) appearance of a bizarre biphasic QRS-T complex at a low rate—omen of cardiac arrest. This is the same sequence as observed with potassium. However, roughly 2–3 times as high a lithium level was necessary to produce a given change as is required of potassium. With the hyperlithemia, it was observed that there was progressive increase in the concentration of serum potassium from about 4.0 mEq/l to about 10 mEq/l. The electrocardiographic effects of lithium may be secondary to its effects on the concentration of potassium in the heart muscle and in the extracellular water or in the ratio of these two.

A critical study of the Shay rat ROBERT J. MADSEN AND HELEN H. RAMSBURG (introduced by M. O. LEE) *Experimental Biology and Medicine Inst., Natl. Insts. of Health, Bethesda, Md*

Large numbers of male Sprague-Dawley rats were preoperatively starved for 24 hours, the pylorus ligated and starvation continued postoperatively for 18 hours, water being withheld. This standard method gave a weight (gm)/volume (cc) of gastric secretion ratio of 12 ± 5 , the pH varied from 1.1 to 1.8 and 80% of such rats developed forestomach ulcerations. The stomachs of these rats were greatly distended but not necessarily to an unphysiological degree as shown by three lines of evidence. The vital dye benzo sky

blue (C.I. 520) was injected intravenously into rats whose stomachs were distended and ulcerated, and simultaneously into control rats whose stomachs were equally distended but because of therapy with aluminum hydroxide had no ulcers. In both cases the dye uniformly stained the tissues proving that capillary circulation was functioning in the ulcerating tissue. Intragastric pressure in these rats averaged 6–7 cm of water. Finally, direct observation showed that capillary flow did exist in the ulcerating tissue. The volume of gastric secretion could be increased by postoperative hydration with saline or decreased by additional preoperative starvation and dehydration. Rats placed on an adequate purified diet 10 days prior to operation and compared to those on a stock diet showed no significant differences postoperatively. Ligation of both vagi, ureters or common bile duct produced a profound reduction in gastric juice volume and forestomachs free of ulceration.

Normal blood sugar in sheep and lambs DAVID E. MANN* AND M. X. ZARROW *Purdue Univ., Lafayette, Ind*

It has been reported that the normal blood sugar of sheep is consistently low compared to that of man. Dukes in *'Physiology of Domestic Animals'* (1935) gave a range of 40–65 mg % and Hitchcock and Phillipson (*J Physiol* 105 42, 1946) reported that 72% of their values were between 38–50 mg % and 16% were lower. A series of blood sugar values were obtained in 4 normal sheep of the Dorset and Shropshire strain throughout the months of November and December. Blood was obtained either from the jugular vein or an ear vein and determinations made by the Folin-Wu micromethod. The average blood sugar for this group was 67 mg % with a range of 56 to 75 mg %. Approximately half of the values were between 70 and 75 mg %. In 3 nursing lambs an average blood sugar of 126 mg % was obtained with a range of 63 to 225 mg %. It is apparent that though there is a tendency towards low blood sugar level in sheep a large percentage of the values approach the lower limits observed for other species. The wide variations observed in the lambs was probably due to the fact that the blood was obtained at different intervals after nursing which would also account for the high concentration of the blood sugar.

Effect of neuro- and adeno-hypophysectomy on water metabolism and on hypothalamic nuclei in the rat THOMAS H. MAREN AND DAVID BODIAN (introduced by E. K. MARSHALL, JR.) *Dept. of Pharmacology and Exper. Therapeutics, and Dept. of Epidemiology, Johns Hopkins Univ., Baltimore, Md*

Hypophysectomies of several types were as-

essed quantitatively by study of serial sections of the head. Cell counts were made of supraoptic and paraventricular nuclei. Hypothalamus and median eminence were uninjured. Sixteen animals were observed for 3-6 months post-operatively. The animals fall into 3 groups on the basis of anatomical and physiological findings. In *Group I* (7 rats) anterior lobe function appeared normal and 55-100% of that gland remained. Water intake was markedly elevated in all cases, and ranged from 100-170 ml/24 hr. In every case, the neurohypophysis was only partially ablated, the amount of normal appearing remnant being 33-71% (av. 50%). Response to water diuresis was normal. The typical anti-diuretic effect of nicotine was abolished in 6 of the 7 rats. In *Group II* (6 rats) the neurohypophysis was also partially ablated, remnant being 12-76% of normal (av. 57%), but the anterior lobe was totally removed with corresponding loss of function. There was no polydipsia. Water diuresis was sharply diminished, but could be restored by administration of desoxycorticosterone. In *Group III* (3 rats), there was subtotal removal of both lobes, anterior remnant was 7-18% and posterior 19-43%. There was mild polydipsia, and moderate water diuresis. Nicotine effect was abolished. In the hypothalamus a striking difference, as yet unexplained, was found between *Groups I* and *II*, where neurohypophysial remnants had similar volumes (50, 57%), but in *Group II* there had also been total adenohypophysectomy. These latter animals showed greater loss in the magnocellular hypothalamic nuclei, this was most notable in the paraventricular, where *Group I* averaged 35% remaining cells, and *Group II* only 16%.

Relation of length to tension in double-function muscles J. E. MARKEE AND M. F. WILLIAMS *

Dept. of Anatomy, Duke Univ., Durham, N. C.

We have previously reported that those thigh muscles such as the gracilis, semitendinosus, and biceps femoris which act as double muscles possess the physiological characteristics of flexors in one part of the muscle, and of extensors in the other part. That is, the flexor portion fatigues more rapidly, develops less tension per unit of weight, and develops effective tension through a larger proportion of the range of shortening of the fibers than does the extensor portion of the same muscle. The present study deals with further details of the ability of the flexor portion of these muscles and some of the flexor muscles which act over the ankle of the dog to develop effective tension through most of the range of movement, whereas the tension developed by the extensor portion of these muscles, or by adjacent extensors is markedly influenced by the length of fibers at the time of the contraction. In the case of the flexor muscles

or flexor portions of the double muscles, increasing the length of the fibers results more rapidly in an increased resting tension and less rapidly in an increased total tension which can be developed during contraction. Consequently, the active tension is influenced less by the length of the fiber than is true of the extensor unit. Flexor muscles or the flexor portion of double muscles are able to exert almost maximum active tension throughout more than three fourths of that range of shortening which the fibers could accomplish *in situ*.

Cholinergic sensitivity in an afferent cerebral system AMEDEO S. MARRAZZI AND C. ROSS HART *

Toxicology Section, Med. Div., Army Chemical Center, Md.

In the past, efferent cortical cells have been activated by large doses of acetylcholine protected by eserine. The size of the doses required has made physiological interpretation difficult. In the cat it has been possible, by submaximally activating the optic tract electrically and recording the evoked post synaptic potentials from the optic cortex, to study the effects of drugs on the 2 synapses between the tract and cortex ((1) MARRAZZI, A. S., *Federation Proc.* 2: 33, 1943). In these experiments, the drugs reached the tissues in a natural fashion through the blood supply and in reasonably small quantities. With intracarotid injection in cats lightly anesthetized with sodium pentobarbital, the following consistent group of findings was obtained: a) acetylcholine, 2.5 gammas, produced a marked, quickly reversible augmentation in the potentials evoked from both optic cortices on stimulating one optic nerve; b) DFP produced a prolonged augmentation; c) atropine sulfate decreased the augmented response. The blocking action of atropine indicates that the anticholinesterase action of DFP was involved. Experiments in progress will test whether the actions may not be localized exclusively to the synapses. The effects of acetylcholine, of an anticholinesterase and of the blocking agent, atropine, illustrate an unequivocal cholinergic sensitivity in the cerebral portion of the optic system and therefore a mechanism potentially capable of participating in synaptic transmission. The mechanisms suggested by the above results and the previously described adrenergic inhibitory effects on the same system 1) could constitute a humoral, perhaps accessory, system transmitting excitation and inhibition in an afferent pathway in the central nervous system.

Quantitative micro-analysis of nucleic acid purines and pyrimidines without prior isolation of the nucleic acids A. MARSHAK AND H. J. VOGEL *

Dept. of Chemistry, New York Univ.—Bellevue Med. Center, New York City

Thirty mg lipid-free, trichloroacetic acid-extracted material are digested in an open tube with 0.16 ml 12 N perchloric acid at 100°C for 1 hour, diluted with water to 1 ml and centrifuged. Aliquots of the supernatant are subjected to paper chromatography. Base recovery (as N) is 97% from calf thymus desoxypentose nucleic acid and 95% from yeast pentose nucleic acid. Lipid- and acid-soluble-free Arbacia sperm and Arbacia eggs contain, respectively, 0.98 and 0.91 gram-moles bases/gram-atom phosphorus. Pentose- and desoxypentose-linked pyrimidines may be estimated since differential splitting is obtained under appropriate conditions. Analyses, as molar ratios relative to adenine

	ADE NINE	GUA NINE	CYTO SINE	URA- CIL	THA- MINE
Arbacia sperm	1.00	0.70	0.64	0.00	1.01
Asterias sperm	1.00	0.69	0.62	0.00	0.91
Arbacia eggs	1.00	1.37	1.06	0.46	0.00
<i>M. tuberculosis</i> (H37Rv)	1.00	1.86	1.92	0.28	0.51
<i>M. tuberculosis</i> (H37Ra)	1.00	2.01	1.86	0.30	0.56
<i>M. sp</i> (M 2)	1.00	1.60	1.21	0.58	0.12
<i>M. sp</i> (B5-1)	1.00	1.64	1.25	0.56	0.12
PNA, yeast	1.00	1.13	0.71	0.73	0.00
DNA, calf thymus	1.00	0.70	0.69	0.00	0.97

Nucleic acids from diverse sources may have similar or very different base ratios. The tetranucleotide theory is not supported. *M. tuberculosis* contains uracil. Since B5-1 contains Feulgen-stainable nuclei while M 2 does not, cytochemical procedures for determining DNA depending upon microscopically visible amounts of Feulgen-positive material are not reliable.

Some liver function tests on dogs in adrenal cortical insufficiency CONSTANCE R. MARTIN* AND W. D. COLLINGS. *Dept. of Physiology, State Univ. of Iowa, Iowa City, and Michigan State College, East Lansing*

Control values for several liver function tests were obtained on 5 dogs. After complete 2-stage adrenalectomy, the tests were repeated with the dogs in varying stages of adrenal insufficiency resulting from treatment with different dosage levels of adrenal cortical extract (ACE) (Eschatin) or desoxycorticosterone acetate (DCA) (Percorten). Bromsulphalein (BSP) excretion was maintained at control levels in the operated animals on maintenance doses of ACE or DCA. BSP retention occurred during periods of inadequate therapy. The retention roughly paralleled rises in serum non-protein nitrogen, but often preceded changes in hematocrit and blood pressure. Changes in serum alkaline phosphatase were inconsistent; 3 animals had increased phosphatase activity during mild insufficiency providing food intake

was adequate. During severe adrenal deficiency, phosphatase fell sharply, probably because of inanition. Albumin/globulin ratios were better maintained with ACE than with DCA, but albumin fell and globulin rose, prior to serum sodium changes, in all mildly adrenal-deficient dogs. Once the ratio fell below control levels, it was not restored by any therapy. The galactose tolerance test was performed on 4 of the dogs. Maintenance of preoperative values was best with ACE, although control values were never achieved in 3 dogs following adrenalectomy. Galactose tolerance always fell as the therapy dose was reduced, but this was not dependent upon hemodynamic changes. Average values follow:

	CON- TROL	MILD INSUFF	SEVERE INSUFF
BSP % ret. 30 min	2.7	5.5	12.6
Serum A/G	2.17	1.63	1.01
B1 Galactose 120 min	0	16	40

Central nervous stimulation by implanted high frequency receiver ALEXANDER MAURO, P. D. WALL, L. M. DAVEY AND A. M. SCHER (introduced by D. H. BARRON). *Lab. of Physiology, Yale Univ. School of Medicine, New Haven, Conn.*

The receiver consists of a parallel resonant circuit of 4 turns of No. 30 enameled wire $\frac{1}{4}$ " sq., tuned by a 50 mmfd condenser. It employs a germanium diode rectifier, and is sealed in an envelope of pure polyethylene. One output lead is connected to a silver plate which projects from the envelope and the 2nd to a monopolar stimulating electrode. Implantation on the motor cortex involves placing the envelope in the sub-apneurotic space and fastening it to the pericranium. The stimulating electrode is inserted through the dura via a bone button and is immobilized by stitching to the dura. The pulser employs a low-power oscillator, driving a power amplifier tuned at 30 megacycles. Repetition rate and pulse width can be widely varied. The pulser can be coupled to the receiver either by a single 5' loop or by 3 loops at right angles to each other around the animal's cage. In the monkey, the receiver has been maintained in use for long periods without complications. The entire system has been operated intermittently during the past 2 years and has proved to be practical. Present uses include investigations on the motor cortex, antiepileptic drugs, control of gastric secretion, and stimulation of the hippocampus and rhinencephalon.

Instantaneous electrocardiographic equipotential lines for right and left bundle branch block and left ventricular hypertrophy ALEXANDER

MAURO,* LOUIS H. NAHUM, HYMAN M. CHIRNOVICH* AND RAJINDER S. SIKAND* *Lab. of Physiology, Yale Univ. School of Medicine, New Haven, Conn.*

The electrocardiographic equipotential lines on the body surface for a given instant have already been charted by the authors for normal humans and anesthetized dogs. In the present study the observations have been extended to patients with intraventricular block of the right and left bundle branch type, as well as to patients with left ventricular hypertrophy. While the plots vary from one individual to another, they all exhibit a) unusual complexity of the individual equipotential lines, b) marked asymmetry of their distribution c) complete absence of any central potential line about which the entire distribution 'rotates' from instant to instant. These observations support the conclusions already derived from the study of normal individuals that at no time in the cardiac cycle does a surface doublet distribution exist.

Exchange of albumin between plasma and lymph

H. S. MAYERSON AND KARLMAN WASSERMAN* *Dept. of Physiology, School of Medicine, Tulane Univ., New Orleans, La.*

Human serum albumin, tagged with radioactive I (I^{131}), has been injected into the jugular veins of dogs and its appearance followed in thoracic duct lymph for periods of from 2-36 hours. Curves drawn from specific activity determinations show that the radioactive iodo-albumin leaves the plasma exponentially at a very slow rate, the average k value being 0.0009. Thus, at the end of 5 hours, only approximately 20% of the radioactive iodo-albumin has left the circulation. A second injection, given approximately 2 hours after the first, yields a disappearance curve the slope of which is similar to that derived from a single injection. Radioactive iodo-albumin first appears in the lymph in measurable count in from 10-20 minutes after the injection depending on the rate of lymph flow. Analysis of curves drawn from specific activity determinations indicate the consistent presence of 3 slopes: 1) a relatively steep slope, lasting about 40 minutes in most experiments, 2) a more gradual slope lasting approximately 70 minutes, 3) a still more gradual slope persisting until equilibrium is reached with respect to the specific activity of albumin in plasma and lymph. This equilibrium, as determined by extrapolation, is reached in approximately 14 hours after the initial injection. Thereafter, the albumin disappears from both tissues at approximately the same rate. Experiments in progress are designed to elucidate the significance of these slopes. Tentatively, it would appear that the initial slope represents the appearance of lymph from the liver and that the second

and more gradual slope indicates the mixture of liver lymph with lymph from the intestines and other more remote areas. The final slope may be interpreted as representing that of radioactive iodo-albumin after the lymph from all parts has become homogeneous with respect to the radioactive iodo-albumin.

Decerebrate rigidity produced by discrete lesions

MARIE J. MAYO (introduced by W. S. WILDE) *Dept. of Physiology, Tulane Univ. School of Medicine, New Orleans, La.*

Attempts were made to imitate the gross transection of the brain-stem necessary to produce decerebrate rigidity by producing multiple discrete lesions with stereotactically directed electrodes in an effort to determine which structures were significantly involved. Since rigidity is best obtained when the brain is transected just above the lateral vestibular nuclei, this level was selected for the placement of the lesions. Cats were placed under ether anesthesia, the lesions placed, and the animal allowed to recover from the anesthesia. Following this the reflexes and muscle tone were observed and the animal photographed. The criterion of totality of rigidity was based on the determination of increase of rigidity by subsequent ischemia produced above the level of the lesion following ligation of the carotid and basilar arteries. It was found that the lesions which consistently produced the best decerebrate rigidity were those which involved both the superior vestibular nuclei and the corticospinal tracts. Lesions in either structure alone produced no effect or flaccidity. Lesions of the superior vestibular nucleus and the medial inhibitory reticular formation produced decerebrate rigidity but to a much less extent than when both the superior vestibular nuclei and the corticospinal tracts were destroyed. The latter rigidity was never increased by subsequent ischemic decerebration.

Effects of vitamin B₁₂ and thyroprotein on growth-inhibiting action of diethylstilbestrol in rats.

JOSEPH MEITES AND H. W. NEWLAND* *Dept. of Physiology and Pharmacology, Michigan State College, East Lansing*

Growth depression induced by diethylstilbestrol in rats has been accounted for on the basis of reduced appetite (MEITES *Am. J. Physiol.* 159:281, 1949). It was hypothesized that these inhibitory effects were induced by increasing certain vitamin needs and/or decreasing thyroid secretion. This hypothesis was tested by treating 5 evenly divided groups of 50 male rats for 20 days. Diethylstilbestrol and thyroprotein were fed in a commercial ration, while B₁₂ was injected subcutaneously at a level of 0.2 μ g daily. During the first 10 days, B₁₂ failed to counteract the growth depression induced by diethylstilbestrol but pro-

tially overcame the effects of the latter during the last 10 days. Thyroprotein plus diethylstilbestrol induced greater growth inhibition than the latter alone. Addition of B_{12} to the diethylstilbestrol-thyroprotein combination completely counteracted the growth-inhibiting action of the latter and only slightly that of the former. Food intake was increased both by B_{12} and thyroprotein.

Measurement of resistance in the human digital vascular circulation MILTON MENDLOWITZ
Mount Sinai Hospital, New York City

The relationship between pressure and flow in the human digital circulation was studied by graded compression of the brachial artery with a special clamp, sympathetic nerve tone having been released by indirect heating. Pressure was measured with a Gaertner capsule and flow with the digital calorimeter. When plotted on logarithmic paper using the formula $Q = aP^k$, a and k being constants, k was found to vary from 0.8 to 1.1. This contrasts with the pressure-flow relationship observed in animal perfusion experiments in which k is 1.4–1.8. This difference is believed to be attributable to the fact that in the vasodilated finger tip the preponderance of flow is through digital arterio-venous anastomoses rather than through capillaries. Poiseuille's law is hence more applicable to the digital circulation than to the circulation as a whole. Application of the law enables measurement of 1) vascular configuration volume index, 2) digital vascular caliber, 3) resistance in dyne seconds per cm^4 , and 4) resistance in dynes. The normal variations and the changes in hypertension and polycythemia are discussed.

Urolipase in normal and depancreatized dogs

H. C. MENG (introduced by CHARLES E. KING)
Dept. of Physiology, Vanderbilt Univ. Med. School, Nashville, Tenn.

The pathological and physiological significance of urinary lipase (urolipase) is poorly understood, and some investigators even question its existence. The purpose of this investigation was to attempt to find the origin of urolipase and determine its significance in relation to fat metabolism. Catheterized urine specimens were obtained from normal healthy dogs, and it can be stated definitely that urolipase appeared in the urine, but there was considerable variation in concentration between different dogs and from time to time in the same dog. Ten of these dogs were given 30 gm. of olive oil/kg. by stomach tube, and 8 of them showed a significant increase of urolipase. However, the increase was not correlated with the increase in serum lipase. Dogs receiving 3 gm. of olive oil/kg. intravenously as a 10% emulsion showed a still more marked elevation of urolipase. Depancreatized dogs showed a somewhat smaller increase of urolipase following intravenous injection

of fat emulsion. It thus seems likely that part of the urolipase originates in the pancreas.

Immediate increase in adrenaline 'sensitivity' of the sympathectomized nictating membrane of the cat following SC-1950 GEORGE W. MEYER*
AND KEITH S. GRIMSON *Dept. of Surgery, Duke Univ. School of Medicine, Durham, N. C.*

Increased contraction of sympathectomized nictating membranes with epinephrine is a phenomenon commonly attributed to degeneration of post-ganglionic fibers. A new quaternary amine, 2,6-dimethyl, diethyl piperidinium bromide, SC-1950, blocks autonomic ganglia and has been used to test this hypothesis. Dose of SC-1950 used was 4 mg/kg. and of epinephrine or nor-epinephrine 5 μ g. Left ganglionectomy and right preganglionic sympathectomy was performed in 9 cats 7–9 days before tests. Then epinephrine in 7 and nor-epinephrine in 2 caused contraction of the left nictating membrane greater than the right. Immediately following first or occasionally second injection of SC-1950 in 8 of the 9 cats, contraction of the left preganglionic side increased. With epinephrine in 6 increase was partial in 4 from an average of 2.5 cm. excursion of the writing lever (Rt.) and 6.1 (L.) before SC-1950 to 4.3 (Rt.) and 6.0 (L.). Increase was complete in 2, average 1.5 (Rt.) and 4.9 (L.) before to 4.8 (Rt.) and 4.9 (L.) after SC-1950. With nor-epinephrine increase was partial in one and complete in one. Epinephrine or nor-epinephrine was given to 3 cats a week after left ganglionectomy, leaving the right normal with no increase on either side following SC-1950. Also, ganglionectomy was performed on each side in 2 cats and a week later contractions were equal and did not change after SC-1950. The isolated superior cervical sympathetic ganglion of the cat a week after decentralization evidently exerts a buffering influence against nictating membrane contraction with epinephrine.

Parathyroid extract hyperphosphaturia in hypoparathyroidism ALEXANDER J. MICHIE AND JEANNETTE MCCONNELL SHOREY (introduced by HOMER W. SMITH) *Harrison Dept. of Surgical Research, School of Medicine, and Hospital, Univ. of Pennsylvania, Philadelphia*

As parathyroid extract causes little or no increase in the minute excretion of phosphate in voided urine or normal subjects we wished to determine the renal mechanism by which parathyroid extract causes hyperphosphaturia in patients suffering from hypoparathyroidism. The subjects had had a previous resection of their thyroid following which they developed symptoms of hypoparathyroidism, i.e. tetany, etc. Their hypocalcemia was treated with either vitamin D or AT-10 supplemented with oral calcium. The vitamin D or AT-10 was stopped a month prior

to the performance of the renal clearances. Renal plasma flow and glomerular filtration rate were determined in the usual manner. Bloods and urines were analyzed so that the minute excretion of phosphate in the bladder urine and the minute tubular reabsorption of phosphate were measured. Then 200 μ of parathyroid extract were given i.v. and these examinations repeated. During the subsequent 3 hour period there was no significant change in the tubular reabsorption of phosphate. However, the amount of phosphate appearing in the bladder urine per minute increased 4-fold. The increase in phosphaturia was secondary to a slight increase in glomerular filtration rate. This caused an increased amount of phosphate to be presented to the tubule which did not respond either by increased or decreasing its phosphate reabsorption rate.

Glycogen deposition in the liver and the interscapular fat body of the mouse LOUISE MICKIEWRIGHT (introduced by J. WAITER WILSON)
Brown Univ., Providence, R. I.

A diurnal cycle of glycogen deposition in the interscapular fat body, similar to that in the liver has been observed in the mouse, this similarity is particularly evident in animals whose feeding is restricted to certain hours. Two groups of mice, aged 7 weeks and 35 weeks, respectively, were allowed to feed between 5 P.M. and 9 P.M. only. Animals were killed at 7 A.M., 3 P.M., 9 P.M., and 1 A.M., the glycogen content of the liver and fat body was studied cytochemically. The amount of glycogen in both liver and fat body was maximal at 1 A.M., at 7 A.M. there was a slight decrease and the minimal level in both was observed at 3 P.M. The glycogen cycle is less clear-cut in animals whose feeding is not restricted. In 35-week-old mice the cycles in the fat body and the liver were similar. The amount of glycogen was highest at 1 A.M. and for the remainder of the 24 hours was much lower and rather constant. In 5-week-old mice the fat body contained the maximal amount at 1 A.M. but the glycogen content of the liver was highest at 9 A.M. In these young mice the lowest content in the liver occurred at 9 P.M. but the lowest amount in the fat was observed either at 9 A.M., 1 P.M. or 5 P.M. Within the interscapular fat body the distribution of glycogen among the cells is not uniform even when the total amount of glycogen is maximal.

Certain effects in dogs of inspiring 15-30% carbon dioxide FLETCHER A. MILLER, E. B. BROWN, AND RICHARD L. VARCO (introduced by OWEN H. WANGENSTEEN) *Dept. of Physiology and Surgery, Univ. of Minnesota, Minneapolis*

Normal mongrel dogs were anesthetized with sufficient sodium pentothal to permit tracheotomy or tracheal intubation. Control respiratory mi-

nute volumes and blood pressures were recorded with the animal anesthetized below the excitation plane. Carbon dioxide oxygen mixtures containing 15, 20, 25, and 30% CO_2 were administered via an inspiratory demand valve regulator. After 30-45 minutes breathing each of these mixtures, the respiratory minute volume was measured and an arterial blood sample drawn for pH and CO_2 content. From these data pCO_2 and BHCO_3 content were calculated and compared with preanesthetic values. High pCO_2 apparently exerts an anesthetic effect as indicated by the lack of need for additional pentothal following administration of 15% or higher CO_2 mixtures. Respiratory depression did not regularly begin until the dogs breathed a mixture containing CO_2 in concentrations greater than 15%. *In vivo* plasma CO_2 absorption curves have been constructed with pCO_2 as great as 300 mm Hg. Maximum BHCO_3 concentration is usually reached at a pCO_2 of 140-160 mm Hg and from this point the increase in total plasma CO_2 is accounted for solely by dissolved CO_2 . Arterial blood pH values of 6.6 to 6.7 have been obtained regularly from the blood of dogs breathing 30% CO_2 for 30-60 minutes.

Unidirectional permeability of the vaginal wall of the rabbit N. MILLMAN,* C. G. HARTMAN, J. STAVORSKI* AND J. BOTTI* *Ortho Research Foundation, Raritan, N. J.*

As has long been known, many classes of chemicals are readily absorbed from the lumen of the vaginal tract, as indicated by their appearance in appreciable quantities in the blood. This is true of such diverse substances as salts, sugars, proteins, dyes, alkaloids, chemotherapeutic agents and antibiotics. However, the experiments here recorded indicate that the reverse process occurs only to a minimal extent, if at all. Thus one may build up tremendous concentrations of substances in the blood for long periods and yet be unable to detect any of them in the vaginal tract. Even when high local concentrations are built up, as by injections of the perineal fasciae, there is no release into the lumen. These findings were confirmed by *in vitro* tests in which the vagina was excised and used as a dialysis membrane, with the mucosal surface on the inside. Chemical and fluid shifts on both sides were noted. When the solution of a test substance was placed inside the 'bag', some of the solute was soon found to have penetrated the wall. On the contrary, when the reverse passage was tested, none of the solute was found on the inside. Occasionally, a water exchange was observed. Substances tried *in vitro* and *in vivo* experiments included NaCl, KI, glucose, antipyrine, sulfanilamide, methylene blue, neutral red, light green, safranin, human blood antigen and antibody.

Effects of pituitary growth hormone in normal and depancreatized cats A E MILMAN AND P DE MOOR (introduced by F D W LUKENS) *George S Cox Medical Research Inst, Univ of Pennsylvania, Philadelphia*

The effect of purified anterior pituitary growth hormone on glucose and nitrogen excretion has been studied in normal and depancreatized cats. Growth hormone produced nitrogen retention in depancreatized cats maintained on constant insulin dosage and food intake. Nitrogen retention occurred in spite of increased glycosuria, but the amount was less than that obtained in normal cats treated for the same 4-day periods at the same dose levels (3 and 10 mg/day). The failure of growth hormone to induce maximal nitrogen retention in animals receiving a fixed insulin dosage and lacking the capacity to augment their own secretion of insulin, supports the hypothesis that in normal animals growth hormone induces the secretion of additional insulin. After withdrawal of the growth hormone, there was an unexpectedly slow return of the glycosuria to pre-injection levels, a phenomenon which is unexplained. Glycosuria developed in one normal cat given 10 mg of growth hormone daily for 3 days. In acute experiments in fasted normal cats, and in diabetic cats deprived of insulin, the intraperitoneal injection of growth hormone produced a depression of the blood amino-nitrogen level in 2-6 hours. This observation, similar to that reported in normal and partially diabetic rats (alloxan), provides the first evidence of an effect of growth hormone on nitrogen metabolism completely independent of insulin.

Recording two-channel photofluorometer for in vivo studies with fluorescein DAVID MINARD AND MAYNARD EICHER *Naval Med Research Inst, Bethesda, Md*

To measure time of appearance of fluorescein after intravenous injection and to record rate of change in fluorescence in 2 tissue areas simultaneously, a recording 2-channel photofluorometer has been constructed, each unit utilizing a photomultiplier tube (RCA 931A) as the photosensitive element and a GE F-5000 mercury vapor lamp as the ultraviolet source. The paired elements are fixed in either arm of a V-shaped holder with a one-inch window at the apex. For deeply situated organs, polished quartz rod extensions serve as 2-way conductors of activating ultraviolet and emitted fluorescence. Dark purple ultraviolet transmitting filters (Corning No 5970) over the U-V sources and yellow filters (Corning No 3486) over the photomultipliers, insure selective sensitivity to wave-lengths emitted from activated fluorescein. An electronically regulated power supply provides stable D C voltages up to 1200 volts to each photomultiplier. The outputs from

the photomultipliers are read directly from panel microammeters or recorded by oscillographic galvanometers (Consolidated type 7-115) with a slit camera. Additional channels permit simultaneous recording of other physiologic variables, such as blood pressure and urine flow. Galvanometer and microammeter sensitivities can be reduced in fixed steps. Bucking current circuits permit zero adjustment at high outputs. The units are standardized against films of graded fluorescence. The instrument is useful in studies on circulation time to brain, skin, kidneys and other areas and in detecting vasomotor reactions in skin and kidneys resulting from the action of drugs, asphyxia, anoxia and nerve stimulation.

Studies on renal cortical ischemia using the recording photofluorometer DAVID MINARD AND ELLIOTT F OSSERMAN (introduced by ALBERT R BEHNKE) *Naval Med Research Inst, Bethesda, Md*

To record repeated observations on both kidneys simultaneously the 2-channel photofluorometer described elsewhere by Minard and Eicher was used in studies of renal cortical ischemia resulting from epinephrine injection, splanchnic nerve stimulation, and asphyxia in anesthetized monkeys, dogs, and rabbits. Arrival of sodium fluorescein at each kidney surface following rapid controlled intravenous injection of small dye doses (2 mg/kg) is recorded as a rising and falling curve of typical form. Failure of injected dye to produce an appreciable increase in fluorescence is the criterion for ischemia. Blood pressure, injection time, and in some experiments urine flow from each kidney are also recorded. Asphyxia and epinephrine in rabbits regularly blocks dye appearance. Epinephrine and splanchnic nerve stimulation in monkeys and dogs produce ischemia but asphyxia is relatively ineffective. In the rabbit denervating one renal pedicle abolishes ischemic responses to asphyxia but not to epinephrine. Preliminary studies indicate anoxia rather than CO₂ accumulation to be responsible for asphyxial ischemia in the innervated rabbit kidney. Active and passive changes in effective area of surface vessels of the intact stained kidney are manifested as changes in fluorescence. Thus in the monkey epinephrine and splanchnic nerve stimulation cause pronounced increases in kidney fluorescence. Bradycardia from peripheral vagal stimulation is associated with a slow rise in fluorescence during periods of asystole and a rapid fall during systole. However no significant changes in kidney fluorescence or in appearance of the typical curve following dye injection result from central sciatic stimulation or bilateral carotid occlusion.

Proteolytic systems in plasma active at acid reactions I ARTHUR MIRSKY, PERRY FUTTERMAN*

AND ROBERT H. BROTH-KAHN *May Inst for Med Research, Jewish Hospital, Cincinnati, Ohio*

Previous studies have demonstrated that pepsinogen is secreted, in part, directly from the gastric peptic cells into the blood stream. Efforts have been made to detect and measure the quantity of circulating pepsinogen. During these studies, it was noted that human and animal plasma contained at least two proteolytic enzymes active at acid reactions. One of these systems exhibits maximum activity at pH 3.5 and does not originate in the gastric mucosa. Another system is active at pH 2 to 2.5. The concentration of this latter system in the blood is apparently related to the activity of the gastric mucosa. It has been demonstrated that much of this activity cannot be attributed to the activation of pepsinogen but is related to the existence in the blood of another proteinase which, like pepsin, is also active at acid reactions. The distribution and some properties of these systems will be described.

Factors influencing intrarenal pressure. A. V. MONTGOMERY (introduced by E. L. PORTER) *Dept of Physiology, Univ of Texas School of Medicine, Galveston*

Intrarenal pressure (IRP) can be dramatically affected by various experimental procedures. Complete renal arterial occlusion or renal decapsulation caused a decrease in IRP. Complete renal venous occlusion or an increase in ureteral pressure causes an increase in IRP, but the effect of either manipulation is diminished by decapsulation. When the renal vein is totally occluded, the IRP is about the same as the pressure on the renal side of the occlusion. That arterial pressure *per se* is not an important component of IRP is indicated by the lack of correlation between systemic arterial pressure and IRP. From these results it is concluded that IRP is similar to the pressure of a fluid contained in an elastic bag. Inside the bag, as well, there are 2 discrete and elastic compartments also filled with fluid. These may be designated as the vascular compartment and the tubular (nephron?) compartment. Any condition which causes dilation of either of these compartments or which causes contraction of the elastic wall of the bag will produce an increase in the pressure of the fluid (IRP) in the bag. It seems likely that the tubular compartment is dilated by increasing ureteral pressure and that an increase in renal venous pressure causes a dilation of the thin-walled venous side of the vascular compartment. But because the walls of the arterial side of the vascular compartment are relatively rigid, changes of pressure within them do not influence IRP.

Critique of the use of sulfanilamide and D₂O for determination of total body water in dogs. P. O. 'B. MONTGOMERY AND M. J. FOGELMAN

(introduced by ARTHUR GROLLMAN) *Dept of Experimental Surgery, Southwestern Med School, Univ of Texas, Dallas*

In the course of studies designed to measure rates of movement of water between various solvent compartments within the body, simultaneous total body water determinations, using D₂O and sulfanilamide were performed on dogs. A known amount of D₂O (0.5 cc/kg/bw) and sulfanilamide (20 mg/kg/bw) were injected intravenously into unanesthetized dogs. Venous blood samples were drawn during intervals up to periods of 2 hours. D₂O was determined by the falling-drop method and sulfanilamide by the method of Bratten and Marshall. Results indicate that equilibration of D₂O or sulfanilamide in whole blood is not attained after 2 hours. Values for total body water calculated from the disappearance curves of D₂O from whole blood vary from 32% to 90% of body weight with an average of 54% body weight. Values for total body water calculated from the disappearance curves of sulfanilamide from whole blood vary from 52% to 97% body weight with an average of 74%. Figures for total body water obtained simultaneously the 2 methods for individual animals cannot be correlated. These discrepancies may be explained by variations in internal diffusion area, and changes in internal convection forces.

Physiological effects of warming, cooling, and exercising the feet during prolonged radial acceleration. LAURENCE E. MOREHOUSE, RICHARD E. HUGHES,* ELIZABETH M. PRANGE* AND JANET WESSEL* *Depts of Physical Education and Aviation Medicine, Univ of Southern California, Los Angeles*

The ability to withstand footward acceleration in aircraft is related to shifts of body fluids. Heat, cold, and exercise in sufficient quantities to alter circulation were applied to the feet before and during 3 minute runs at 3.5 g on the human centrifuge. Ear opacity and pulse, thermistor temperature measurements, and foot size determinations were recorded in 9 male subjects. When the feet were first immersed in hot water before centrifugation, the circulation to the head was diminished. No further circulatory embarrassment was observed during acceleration and the recovery was more rapid when the feet were edematous due to heat. Immersing the feet in ice water raised the pulse rate but did not affect the head circulation either during acceleration or recovery. Exercise also increased the pulse rate but slightly reduced head circulation during acceleration and recovery. It is felt that foot temperature and exercise probably do not affect physiological responses to acceleration enough to influence g endurance.

Investigation of polarometric method for oxygen tension in blood with a rotating platinum elec-

trode EDWARD H MORGAN AND GABRIEL G NAHAS (introduced by HOWARD B BURCHELL) *Mayo Foundation, Rochester, Minn*

In accordance with principles outlined by Kolt-hoff and by Laitenen, a rotating platinum electrode and external circuit were constructed and adapted for measuring oxygen tension in 1.5 ml samples of whole human blood. Coating of the platinum electrode with a film of silicone (dri-film 9987) was found to delay the loss of reactivity of the platinum surface when it was in contact with blood. In samples of blood equilibrated with mixtures of O_2 and CO_2 , in tonometers at $25^\circ C$, the diffusion currents obtained at an applied EMF of $-0.8 V$ varied not only with pO_2 but also with pCO_2 . When the pCO_2 was maintained within ± 3 mm Hg, current values were linearly proportional to pO_2 in the range from 50 to 250 mm pO_2 . Increase in pCO_2 yielded higher current for a given pO_2 . The mean difference of duplicate measurements of the diffusion current obtained from 28 blood specimens at various oxygen tensions was 0.16 microampere (range 0.068 microampere) which was equivalent to 3.3 mm Hg pO_2 (range 0-14.3 mm Hg). Thus far, however, sensitivity and reproducibility of results adequate for routine use have not been attained because of uncontrolled and not completely understood vagaries of the platinum electrode.

Failure of cold pressor response to correlate with personality tests CAMPBELL MOSES, DOROTHY W HULMER* AND DORA CAPWELL* *Addison H Gibson Lab, Univ of Pittsburgh, and the Allegheny Vocational Counseling Center, Pittsburgh, Penna*

The cold pressor response of Hines and Brown (*Am Heart J* 11 1, 1936) and several personality tests were studied in 167 selected individuals. Of this group 60 gave a normal pressor response and 60 were classified as hyperreactors. Forty-seven subjects with essential hypertension were similarly tested. No significant correlation between the cold pressor response and the Bernreuter Personality Inventory, the Rosensweig Picture Frustration Test, the Guilford-Martin Personnel Inventory or the Kuder Preference Record was obtained in either the normotensive, the hypertensive or the hyperreactor subjects. It is suggested that the cold pressor response is of such complex origin that it cannot be correlated with a single personality test.

Comparison of step-up and treadmill exercise using arterial blood and respiratory gas exchange measurements HURLEY L MOTLEY AND JOSEPH F TOMASHEFSKI* *Cardio-Respiratory Lab, Barton Memorial Division of Jefferson Hospital, and Dept of Medicine, Jefferson Medical College Philadelphia, Penna*

A comparison of the variations in respiratory gas exchange measurements during rest and exercise is valuable for appraisal of pulmonary function status in man. The step-up exercise test (30 step-ups 20 cm high in one minute) was compared with treadmill exercise (rate and tilt adjusted so that the patient can continue for 15 minutes). Gas and arterial blood samples and pressures were taken after 10 minutes of treadmill exercise (allowed to attain a steady state). Studies on 54 patients with fibrosis and various degrees of pulmonary emphysema are reported.

	ART O_2 SAT	O_2 CONS	CO_2 OUTPUT	VENTIL. VOL.
	%	cc/sq m/min		l/sq m/min
Rest	92.9	145	118	4.7
Step-up	91.6	474	355	12.2
Treadmill	93.4	484	400	12.6

In 17 cases the treadmill exercise produced a slight decrease in arterial oxygen saturation, in 24 there was a slight increase and in 13 there was a significant increase (3% +). Step-up exercise is a more severe test for the emphysematous patient than a treadmill exercise which can be maintained for 15 minutes. Respiration rate, blood pressure, pulse rate and percentage of oxygen removed did not vary significantly between the two methods of exercise, but in the 36 cases with a significant degree of emphysema (residual air over 35% of total lung volume) the arterial oxygen saturation was decreased more with step-up exercise. The step-up test is as satisfactory as the treadmill in providing information essential for evaluation of pulmonary function impairment.

Polarographic analysis of spinal fluid as an aid in the diagnosis of poliomyelitis OTTO H MÜLLER *Dept of Physiology, Syracuse Univ College of Medicine, Syracuse, N Y*

In a polarographic study of spinal fluid in poliomyelitis and other diseases it was found that the procedure used for determination of the 'protein index' (MÜLLER AND DAVIS, *Arch Biochem* 15 39, 1947) was not applicable because of the small amounts of protein involved. The following technique, similar to that of Homolka and Krupička (*Čas lékařu čes* 87 1326, 1948) was more suitable. To 1.0 ml of spinal fluid is added 1.0 ml of 0.1 N KOH. Of this mixture, a first sample of 0.8 ml is added immediately to 2.0 ml of a buffer consisting of 0.001 M $Co(NH_3)_6Cl_2$, 0.1 N NH_4Cl and 0.1 N NH_4OH and then analyzed polarographically. A second sample of 0.8 ml, taken after 45 minutes is similarly analyzed. The results of the last analysis are expressed in percent of the starting values. In an investigation of over 120 spinal fluids it was

found that in 'normal' samples not only were the starting values small but also the changes produced by digestion. In contrast to this the starting values in poliomyelitis are usually very much higher and increase by 100% or more during digestion. Observations made so far indicate that this change from normal can be correlated with intensity of the disease. Return to normal during convalescence appears to be slower for the polarographic values than for other clinical findings. These results suggest that the proteins of spinal fluid not only change in quantity but also in quality in poliomyelitis.

Uptake of phosphate by frog axons L. J. MUIRHEAD
(introduced by FRANK BRINK) *Dept of Biophysics, Johns Hopkins Univ., Baltimore, Md*

A method has been devised for continuously recording the variation in P^{32} content of axons, while allowing electrical stimulation, changes in gas tensions, or other chemical variations in the surrounding fluid. Over a period of 10 hours, a nerve at 20°C takes up P^{32} to a concentration 5 to 10 times that of the external solution. Phosphate uptake at 0°C in O_2 or at 20°C in N_2 , or at 20°C in O_2 with 0.1 mM azide, is zero. The temperature coefficient of uptake (Q_{10}) ca. 2.5 over the range 10-30°C. At temperatures higher than 30°C the axon deteriorates rapidly with respect to conduction but P_3 uptake is maintained for several hours after conduction has failed. Removal of the connective tissue sheath has been shown to increase the P^{32} uptake to slightly more than twice the normal rate. Stimulation at frequencies of from 60-120/sec completely blocks the uptake of P^{32} .

Effect of repeated injections of epinephrine on self-selection of diet in rats, with special reference to sodium and potassium LOUIS P. MUNAN* AND ERRETT C. ALBRITTON *Dept of Physiology, George Washington Univ. School of Medicine, Washington D C*

Subcutaneously injected epinephrine altered, in opposing fashion, the self-selection of salt solutions offered continuously to two strains of rats. Female rats of the Sprague-Dawley and Long-Evans strains were divided into four groups of ten each and maintained on a synthetic diet free of sodium, potassium, chloride, and inorganic phosphate. They were offered separately water and 3% solutions of the missing salts, namely, NaCl, NaH_2PO_4 , KCl, and KH_2PO_4 . Epinephrine injections were given once and later twice daily in isotonic saline in dosage of .02-.04 mg epinephrine/100 gm of body weight. The control groups received an equal volume of isotonic saline at the same time intervals. In the Long-Evans rats, the Na/K intake ratio was smaller in the experimental than in the control group due largely to an increased potassium intake by the experimental animals. In the Sprague-Dawley rats, the Na/K

intake ratio was greater in the experimental than in the control group, due largely to an increased sodium intake by the experimental animals. These findings point to a species difference in the salt function of the adrenal cortex under epinephrine stress.

Net splanchnic glucose production in normal man and in various disease states JACK D. MYERS
(introduced by WALTER KEMPNER) *Dept of Medicine, Duke Univ. School of Medicine, Durham, N C*

The hepatic blood flow, by the bromsulphalein technique, and the glucose difference between hepatic venous and arterial bloods has been measured in a group of 43 control human subjects and in a series of patients with various diseases. In the fasting state, the hepatic venous glucose concentration always exceeds the arterial concentration. Thus the product of the hepatic blood flow (HBF) and the hepatic venous-arterial glucose difference (GD) provides an estimation of the net splanchnic glucose output (SGO). This quantity is less than the actual hepatic glucose production by that amount of glucose which is utilized by the various viscera of the portal venous circulation. The mean HBF in 43 control subjects was 812 ± 24 (S.E.) ml/minute/square meter of body surface. The mean GD was 8.7 ± 0.4 mg%. This provides a mean SGO of 68 ± 4 mg/min/m². In 9 patients with diabetes controlled by insulin, neither the GD nor the SGO varied significantly from the control values. Twelve patients with Laennec's cirrhosis of the liver had a mean GD of 7.7 ± 0.7 mg% (not significantly subnormal) but a reduction in SGO to 52 ± 5 mg/min/m² because of moderate decreases in HBF. In 8 subjects with congestive heart failure in whom the HBF was strikingly reduced, the GD was only moderately increased to 11.5 ± 1.0 mg%, providing a SGO which was subnormal at a value of 50 ± 4 mg/min/m². Ten patients with hyperthyroidism had mild but not significantly elevated GD and SGO.

Application of buffered paper strips to the chromatography of polymyxins HAROLD A. NASH AND A. R. SMASHER (introduced by CARL A. BUNDE)
Research Dept., Pitman-Moore Co., Indianapolis, Ind

To achieve resolution of the polymyxins, the use of strips treated with buffer solutions previous to descending development with n-butanol was investigated. In the acid range, R_f values were found to be less affected by the pH of the buffer than by the concentration of salts in the buffer system. In a given system and at a fixed pH, the R_f values could be partially correlated with distribution coefficients and with hydration of the paper strips as affected by the buffer system. At low buffer concentrations, where hydration effects were relatively constant, different salts were

found to have different effects on Rf values even when the effects on distribution coefficients were the same. In general, di- and trivalent anions were much less effective in increasing Rf values than the univalent anions tried. By proper choice of buffer system, the Rf values of the polymyxins could be manipulated from less than 0.1 to 1.0. For routine work the buffer system, 0.2 M glycine to pH 2.5 with concentrated HCl was adopted. With this system Rf values of the polymyxins were A, 0.18, D, 0.38, E, 0.54, and B, 0.56.

Electrical activity of single muscle fibers at the neuro-muscular junction

WILLIAM L. NASTUK
Dept. of Physiology, College of Physicians and Surgeons, Columbia Univ., New York City

Utilizing the technique previously reported (NASTUK, W. L. AND A. L. HODGKIN *J. Cell & Comp. Physiol.* In press) microelectrodes have been inserted into single muscle fibers of frog sartorius at the neuro-muscular junction. The muscle was placed in Ringer's solution (22°C), single fibers were impaled at a point averaging 42 μ from the center of the junction, and a stimulus was applied to the nerve. The recordings show an end plate potential which rises sharply from the baseline to 42 mv (av) in 0.3 msec. At this level a propagated action potential originates and the membrane is depolarized more rapidly. Repolarization begins at the usual rate but is apparently hindered by the endurance of the original end plate disturbance as evidenced by an abrupt diminution in rate. Average data obtained at the junction are: resting potential 90 mv, action potential 117 mv, peak end plate potential 101 mv. Average data obtained at a point distant from the end plate are: resting potential 91 mv, action potential 123 mv. After 30 min equilibration in Ringer's solution (23.8°C) containing d-tubocurarine chloride (1.4 μ M/l) blocking of some junctions occurs. At such junctions the end plate potential is greatly diminished or absent. For functions still functioning, the end plate potential rises more slowly requiring 0.5 msec to reach 46 mv (av), at which level a propagated action potential originates. Typical data obtained at a point averaging 55 μ from the center of the junction are: resting potential 90 mv, action potential 116 mv, peak end plate potential (when measureable) 106 mv.

Influence of muscular exercise on uric acid excretion in man

JOHN NICHOLS* AND A. T. MILLER, JR.
Lab. of Applied Physiology, Univ. of North Carolina, Chapel Hill

Strenuous exercise (running on a motor-driven treadmill for 1 minute at 10 miles/hour, 17.5% grade) during a state of water diuresis depressed urine flow, glomerular filtration rate (allantoin clearance) and uric acid clearance to 30, 40 and

30% respectively of the pre-exercise values. Urine flow and glomerular filtration rate returned to normal within 10 minutes after cessation of exercise, but uric acid clearance remained depressed for about one hour. Following the suggestion of Quick (*J. Biol. Chem.* 110: 107, 1935) that the excretion of uric acid is influenced by the blood lactate concentration, a second series of experiments was performed. A 10-minute period of moderate exercise (treadmill running at 6 miles/hour, zero grade) resulted in a very small rise in blood lactate and a slight depression of uric acid clearance. When, however, the subject breathed 8% oxygen in nitrogen during the same type of experiment, the rise in blood lactate was considerably greater and there was a marked depression of uric acid clearance. It is concluded that the diminished clearance of uric acid during exercise and recovery is related to the elevated blood lactate level. The basis of this effect is being investigated.

Simultaneous blood volume determinations in dogs with dye (T-1824), carbon monoxide and radioactive iron Fe^{55}

J. L. NICKERSON, L. M. SHARPE,* W. S. ROOT, T. C. FLEMING* AND M. I. GREGERSEN

Dept. of Physiology, College of Physicians and Surgeons, Columbia Univ., New York City, and Brookhaven Natl. Lab., Upton, N. Y.

Measurements of the blood volume in dogs were made using simultaneously the three following techniques: 1) the T-1824 dye method as described by Gregersen, 2) the carbon monoxide method according to the technique developed by Roughton and Root, and 3) the radioactive iron (Fe^{55}) method using tagged erythrocytes from a donor dog. Beaker experiments on known volumes (50 cc) of blood were run concurrently with the *in vivo* tests in order to check the accuracy of the radioactive iron determinations. In 16 beaker experiments the mean volume determined by radioactive iron differed by only one-half of one % from the true volume; the standard deviation being 3%. In 7 technically satisfactory experiments, the mean value of the blood volume measured by the carbon monoxide method was 2% above the value obtained with T-1824, whereas the mean value obtained with the iron method was 11% below that given by the dye. The latter difference is beyond the limit of experimental error. It is therefore considered to be of physiological significance and not explainable by lack of precision in any of the methods.

Responses of blood vessels of the bat's wing to epinephrine and nor-epinephrine

PAUL A. NICOLL
Dept. of Physiology, Harvard Med. School, Boston, Mass., and the Dept. of Physiology, Indiana Univ., Bloomington

Direct microscopic observations were made of

wing vessels in unanesthetized animals with their wing nerve supply either normal or acutely sectioned, or partially degenerated. The substances tested were administered in various ways of which the most efficient was direct topical application on a small area from which the epithelium had been removed on one side. This procedure produced minimal injury, as evidenced by the normal flow, vasomotion and responses of the exposed vessels. Effective concentrations of either epinephrine or nor-epinephrine always constricted the arteries and arterioles. Dilatation was never observed. In structures that normally exhibit rhythmical active vasomotion, such as terminal arterioles, pre-capillary sphincters and venous vessels, both substances increased the magnitude and duration of the constrictor phase. Minimal effective concentrations of applied solutions of epinephrine were between 1×10^{-9} and 5×10^{-8} gm/ml. Nor-epinephrine in comparable tests usually appeared slightly less effective. However, the pH of the applied solutions, the time elapsing between the final dilution and application to the test site, and several other factors so modified the apparent minimal effective concentrations thus determined as to raise serious doubts of the significance of comparing functional responses in terms of limited quantitative differences.

Effects of azide and ATP on retinal potentials

WERNER K. NOELL (introduced by HARRY F. ADLER). *USAF School of Aviation Medicine, Randolph Field, Tex*

In rabbits, rapid intravenous injection of azide is immediately followed by a rise of the resting potential of the eye which within 3 seconds reaches values more than 5 mv above the control level. The decay of this potential depends on the dosage, being a matter of seconds with 1 mg sodium azide/kg body weight. With some delay the rise of the resting potential is followed by an increase in the rate of the spontaneous discharges of the optic fibers reaching values comparable to those obtained by strong illumination. There are also marked changes in the electroretinogram. Reduced and enhanced responsiveness of all components of the electroretinogram are related to the momentary size of the potential change induced. The effect of azide on the electroretinogram is qualitatively similar in frog, cat and rabbit, while the effects of anoxia and iodoacetate vary with the species. The action of azide is interpreted as an inhibition of adenosinetriphosphatase. Essentially the same effects can be obtained by intracarotid injection of adenosinetriphosphate (ATP). Late effects, however, of azide and ATP differ significantly. It appears that ATP and ATPase are essential links in the mechanisms which lead to retinal excitation after illumination.

Slow intravenous injection of large amounts of azide causes inexcitability of optic nerve fibers in rabbits. This may result from its action on other enzyme systems.

Metabolism of tetraethylthiuramdisulfide (Antabuse) WIKTOR W. NOWINSKI, THOMAS P. EDWARDS* AND JAMES P. ELLIS* *Dept of Neuropsychiatry and Tissue Culture Lab, Univ of Texas, Med Branch, Galveston*

It was shown in this laboratory (EDWARDS, *Texas Repts Biol Med* 7: 684, 1949) that Antabuse inhibits 85% of cellular respiration as measured by the oxygen uptake of rat liver homogenates (Warburg technique). In an attempt to elucidate the mechanism of the breakdown of Antabuse in the body, the possible reduction of the molecule was investigated with the Thunberg method. It was found that the reaction time of the digests containing rat liver homogenate and Antabuse (with alcohol as substrate) was 2 to 3 times longer than that without Antabuse. From these results, it was supposed that Antabuse may act in the body as a competitive hydrogen acceptor (at least 4 hydrogens seem to be necessary in order to reduce one molecule of tetraethylthiuramdisulfide) and that inhibition of cellular respiration, as demonstrated by Edwards, could be attributed to this process. To prove this hypothesis, experiments in Warburg manometers were carried out, in which ascorbic acid acted as an additional hydrogen donor. It was found that the inhibition caused by Antabuse could be completely overcome by addition of 20 mg ascorbic acid/Warburg vessel, the actual figures of averages being -125.16 cmm oxygen uptake in one hour, for homogenate plus ascorbic acid and -137.34 for homogenate with Antabuse and ascorbic acid, whereas Antabuse alone gave an inhibition of oxygen uptake of practically 100%. In experiments where smaller amounts of ascorbic acid were present in the system, the reversal of inhibition was accordingly diminished, the averages were -117.21 for control (homogenate and ascorbic acid), -83.18 for Antabuse and ascorbic acid, and -32.87 for homogenate with Antabuse only. In these experiments, 6 mg ascorbic acid vessel restored over 50% respiration. From these experiments, we conclude that tetraethylthiuramdisulfide acts as a competitive hydrogen acceptor and is the cause of inhibition of cellular respiration.

Further proof of the aspiratory effect of inspiration on right atrial inflow DAVID F. OPDYKE AND WILLIAM H. VAN NOATE* *Dept of Physiology, Western Reserve Univ Med School, Cleveland, Ohio*

Although the preponderance of evidence supports the view that blood is aspirated into the

thorax by the act of inspiration, there are opinions to the contrary. It is established that effective right atrial pressure increases during inspiration. However, such changes can be explained either by an increased pulmonary resistance or by an increased right atrial inflow. Indirect evidence that the inspiratory increase of effective right atrial pressure is due to an increased atrial inflow is provided by careful measurements of phasic effective right atrial pressure. The slope of the effective right atrial pressure gradient during the interval from the beginning of ventricular isometric contraction (Z point) to just before the opening of the tricuspid valve (V point) is dependent only upon the volume of atrial inflow since during this time there is no ventricular filling. In every case studied the slope of the Z to V gradient increased during inspiration.

Blood levels of cyclopropane and ether in relation to epinephrine-induced cardiac arrhythmias

M J OPPENHEIMER, E M GREISHEIMER, DOROTHY ELLIS AND SHIRLEY FRIDAY *Dept of Physiology, Temple Univ School of Medicine, Philadelphia, Penna*

Kety (personal communication) has developed a method for determining cyclopropane and ether in blood when both are present. Epinephrine (0.2–0.4 cc of 1:10,000/kg, rapidly) by vein caused ventricular premature systoles and tachycardia in 18 dogs at blood levels of 4.2 to 9.97 vol % cyclopropane. Three dogs developed ventricular fibrillation at 7.69 to 8.33 vol % when the dose of epinephrine was increased. Ether in blood concentrations of 0.30 to 1.70 cc/liter in 8 dogs decreased or entirely prevented the premature systoles, ventricular tachycardia and attendant falls in blood pressure. Analysis of the site of origin of these arrhythmias by simultaneous recording of three unipolar leads (NAHUM, CHERNOFF AND KAUFMAN *Am J Physiology*, 157:248, 1949) has indicated that most of these originate in the right ventricle (13 out of 20) equally distributed between anterior and posterior surfaces.

Relation between normal human electroencephalogram and Rorschach test factors

ROBERT H OSTER AND LEAH MILLER PROUTT* *Depts of Physiology, Schools of Dentistry and Medicine, Univ of Maryland, Baltimore*

An attempt was made to correlate the EEG alpha rate and index with Rorschach test factors on 99 medical students and school personnel. Cortical potentials were recorded from prefrontal and occipital electrodes under standard conditions. Alpha index was determined for a 30 second tracing for both cortical areas, alpha frequency, by the time required for 5 alpha waves measured in 5 different parts of each record. The Rorschach test was given by the group method of the Har-

rower-Erickson and Steiner (Springfield C C Thomas, 1945) with written responses to a 3-minute review of each blot, followed by a 2-minute review to allow orientation of responses and classification as to F, M, C, CF, FC and Sh. The latter period constituted a modified associational period. The written responses were scored according to Rorschach and Beck, (*Rorschach's Test, I and II* New York Grune and Stratton, 1946). The Rorschach test factors A%, Z, TR, M/sum C, C + CF/FC, and P were plotted against the alpha index, and A% and TR against alpha rate. Although the plot of the composite factor C + CF/FC (here used as a stability indicator) against alpha index has a linear relationship, the statistical evaluation revealed no positive correlation coefficient value. The lack of a positive quantitative correlation between the alpha activity and personality type under these test conditions when compared with the general relationships suggested by other workers (Trans Am Neurol 63:167, 1937, *Brain* 59:366, 1936), may be attributed to inherent difficulties in making accurate measurements of personality factors and alpha indices.

Studies on acclimatization of mice to high carbon dioxide and to low oxygen

ARTHUR B OTIS *Dept of Physiology and Vital Economics, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*

Mice will survive for at least a week when placed in a mixture of 20% CO₂, 21% O₂ and 59% N₂. Such an exposure increases the tolerance of the animals to 35% CO₂ but sudden removal to room air may result in convulsions which are often fatal. If the CO₂ concentration is reduced more gradually no difficulty is encountered. Normal mice when exposed to 35% CO₂-67% O₂ retain the righting reflex for only about 3 minutes, but mice which have been exposed for one week to 15% CO₂ retain the righting reflex for at least 30 minutes when exposed to the higher concentration. If mice which have been living in 15% CO₂ are removed to air, the tolerance to 35% CO₂ becomes, after 3 days, the same as that of normal mice. The principal changes observed to occur in mice chronically exposed to 15% or 20% are an apparent increased ventilation, a drop in body temperature, loss of weight and an increase in the alkaline reserve of the blood which is of the magnitude necessary to return the plasma toward the normal pH. Mice which have been exposed to 10% oxygen for 7 days show the same tolerance (as judged by time of maintenance of the righting reflex) to 35% CO₂ as do normal mice.

Ionic alterations in chickens infected with *P. gallinaceum* RICHARD R OVERMAN, ANNE C BASS* AND T H TOMLINSON, JR* *Dept of*

Physiology, Univ of Tennessee College of Medicine and Lab of Tropical Diseases, USPHS, Memphis, Tenn

Flame photometric analyses for Na and K and chemical analysis for Cl were carried out on both plasma and packed erythrocytes of 1) normal chickens, 2) chickens infected with *P. gallinaceum* and showing a) 1-100 parasitized cells per 10,000 RBC, b) 100-3000, c) 3000-5000, d) 5000-7500 and e) over 7500, 3) chickens which had spontaneously recovered from a malaria infection, 4) a series of 'refractory' chickens, and 5) chickens inoculated with EE forms of *P. gallinaceum*. Normal values (average of 9 determinations) were as follows: Plasma Na, 153.7 mEq/l, Plasma K, 6.0 mEq/l, Plasma Cl, 120.7 mEq/l, Erythrocyte Na, 18.0 mEq/l, erythrocyte K, 118.8 mEq/l, Erythrocyte Cl, 127.9 mEq/l. Generally speaking, progressive alterations in ion distribution in infected chickens of group 2 occurred as follows: 1) a reduction in plasma Na concentration, 2) a rise in plasma K, 3) a reduction in plasma Cl, 4) an increase in cellular (erythrocyte) Na and, 5) a reduction in cell K. In chickens showing the higher parasitemias the increase in plasma K averaged 48%, the increase in erythrocyte Na 298%, and the reduction in cell K averaged 36%. Chickens which had 'recovered' showed normal average ionic concentrations in both plasma and cells as did the 'refractory' animals and those inoculated with EE bodies. These changes are entirely similar to those reported by Overman for *P. knowlesi* infected monkeys and human with *P. vivax* or *P. falciparum* infections.

Water and electrolyte changes in rat intestine after total body x-radiation E. E. PAINTER AND E. W. PULLMAN * *Univ of Illinois, College of Medicine, Chicago, Ill*

Preliminary experiments carried out on the small intestine of 220-gm male rats before and after a single dose of total body x-radiation (LD₇₀) indicate that increases in sodium content can be correlated with decreases in potassium and with increases in chloride and water content in the first few days after radiation. These increases in sodium content of the intestine have been confirmed by radioactive sodium studies reported earlier by us (*Quart Report, Biol Div, Argonne National Laboratory*, p 88, Nov, 1948). That increase in sodium is in part related to an increase in extracellular fluid content of x-irradiated animals and in part related to the exchange of sodium for potassium in gut cells appears to be a valid conclusion from our results.

Molecular diffusion and filtration from the capillary circulation of mammalian muscle J. R. PAPPELHEIMER, E. M. RENKIN* AND L. M. BOR-

RERO * *Dept of Physiology, Harvard Med School, Boston, Mass*

Inulin, sucrose, glucose, urea or NaCl were introduced suddenly into arterial blood supplying the isolated perfused hindlimb muscles of the cat. The osmotic activity of each molecular species tending to draw fluid from tissue spaces to capillary blood was counterbalanced by continual adjustment of mean capillary pressure by known amounts just sufficient to prevent net fluid exchange. Under these conditions the changes of mean capillary pressure with time are considered to reflect the diffusion rates of the test molecules across the capillary walls and into the tissue spaces. The half-time of the diffusion process is approximately inversely proportional to the free diffusion constant of the molecular species and to the ease with which fluid passes through the capillary membranes under the influence of a known hydrostatic head of pressure (the filtration coefficient). The half-times are independent of blood flow and of tissue fluid volume in the ranges so far investigated. The data indicate that diffusion of substances across the capillary walls occurs many times more slowly than through a watery solution of equivalent surface area (free diffusion). If the capillary exchange occurs through cylindrical pores or rectangular slits in the capillary walls then the collective area of such openings is less than 2% of the total capillary surface. Combination of filtration data with diffusion data is theoretically capable of yielding information concerning the number and dimensions of ultramicroscopic openings in the capillary walls which would account for the experimental results.

Glucose, pH and potassium retention in red cells

A. K. PARPART AND JAMES W. GREEN * *Dept of Biology, Princeton Univ, Princeton, N. J*

Defibrinated rabbit blood was incubated at 35° C for periods up to 50 hours and a study made of the potassium-sodium exchanges which occurred in the red cells at intervals during this time under a variety of pH and glucose changes. Experiments were made to compare the influence of pH and of glucose utilization on potassium retention. Potassium retention has been studied at several pH's (6.2-7.4) with and without the addition of glucose. Phosphate buffers were used. Results indicate that while glucose utilization is an important factor, there is a very marked, and even over-shadowing, effect of pH, within a certain range, on potassium retention irrespective of glucose utilization. In addition, effects of inhibitors of glycolytic activity have been examined.

Absorption of vibratory energy by human body surface H. O. PARRACK, HENNING VON GIERKE, *

HANS OESTREICHER* AND WOLF W. VON WITTERN* *Aero Med Lab, Air Materiel Command, Wright-Patterson Air Force Base, Dayton, Ohio*

Measurements were made of the response of the body surface to mechanical vibrations. Three methods were used in overlapping frequency ranges so as to span a total frequency range of 20-20,000 cps. The results are consistent and describe the mechanical impedance of the body surface and the elastic properties of the tissue. The impedance consists of a frictional resistance and reactance. The resistance is proportional to the square root of the frequency. The reactance is an elastance varying inversely with frequency up to about 50 cps where it becomes zero. Above this frequency the reactance is an inertance that is proportional to frequency throughout the measured range. The vibratory energy absorbed at the body surface and converted to heat in the tissues may be calculated from the impedance. From these results was developed a theory on the mechanical behavior of the vibrating body tissue that considered the tissue as an elastic medium with viscosity. For such a model, and for the frequency range 20-20,000 cps, equivoluminal shear waves with velocities less than sound are predominant. It is only at still higher frequencies that compression waves play an important role. The theory also explains the surface waves observed experimentally.

Changes of electrical potential of the ventral roots of the spinal frog resulting from reflex stimulation LLOYD D. PARTRIDGE* AND ROBERT GESELL *Physiology Laboratory, Univ of Michigan, Ann Arbor*

Single and repetitive electrical stimuli were delivered by a square wave generator. Changes of electrical potential were recorded with the aid of a D C amplifier and a cathode ray oscillograph. One leading off electrode was placed on the ventral root near its point of exit from the cord, the other electrode about one cm. more distal. Each stimulus was found to produce a sudden increase of negativity of the proximal electrode with respect to the distal electrode, possibly the result of a sudden liberation of acetylcholine at the synapse. The rate of subsequent decay of this negativity was in approximate agreement with the law of mass action as applied to enzymatic destruction of acetylcholine. Repetitive stimulation showed, in agreement with Barron and Matthews, a step-like increase of initial negativity. Such increased negativity was followed by a correspondingly increased rate of initial decay at cessation of stimulation. Action potentials, when they occurred, varied in number directly with intensity of the slow potentials. These findings are thought to support the theory of temporal summation

reported by Frev and Gesell at the 1949 meeting of the Physiological Society. They do not, however, preclude the participation of several factors contributory to the decay of electrotonic potentials.

Studies on in vitro inactivation of alpha-estradiol by infantile, malignant and cirrhotic rat liver KARL E. PASCHKIS AND R. H. DEMEIO* *Div of Endocrine and Cancer Research, Jefferson Med College, Philadelphia, Penna*

Inactivation of alpha-estradiol by liver slices and liver homogenates has been extensively studied. Experiments reported here show that the liver of rats, 6 days of age, have a good inactivating power. Studies were also performed on rats treated with the carcinogen 2-acetaminofluorene, livers from animals killed at a stage where no cancer had yet developed showed good inactivating capacity. Homogenates of malignant hepatomas induced both by 2-acetaminofluorene and p-dimethylaminoazobenzene also showed good inactivating power. We have previously reported good inactivation to be present in starved rats (*Endocrinology* 43: 97, 1948) and in rats treated with carbontetrachloride (*Endocrinology* 33: 309, 1943). It is concluded that the *in vitro* action of liver upon estradiol is present early in life, and over a wide range of abnormal conditions, the system or systems involved appear to be very resistant to damage. This is in marked contradistinction to the overall handling of estrogens *in vivo*, in which the excretory function of the liver plays a large role in addition to the metabolizing action, this overall handling and disposition of estrogens *in vivo* is known to be extremely sensitive, and impaired even by minor, 'subclinical' liver damage.

Elimination of bromide from serum and cerebrospinal fluid S. I. PATRICK* AND G. S. EADIE *Dept of Physiology and Pharmacology, Duke Univ School of Medicine, Durham, N. C.*

Serial cerebrospinal fluid and serum bromide determinations were made simultaneously in 3 patients and 6 dogs with high bromide levels by a new photoelectric method described elsewhere. Bromide concentrations and percentage replacement of chloride were invariably less in the spinal fluid than in serum, this was true even during excretion, i. e. when bromide was passing out of the spinal fluid into blood and so to the kidney. This is taken as evidence for secretion of bromide into the blood stream, presumably by the Pacchionian bodies. Other evidence also indicates that spinal fluid is not in equilibrium with serum, and the ratio spinal fluid bromide/serum bromide is thought to be a physiological rather than a physical ratio. No evidence was found for increased permeability of the choroid plexus at

high bromide levels, evidence for this previously adduced by others is explained by inaccuracies in the chemical methods employed. Addition of chloride to the diet increases the rate of bromide elimination only slightly, the increase is of the order of magnitude of differences in individual rates of excretion.

Cortical receptive zone of the chorda tympani

HARRY D. PATTON AND V. E. AMASSIAN * *Dept of Physiology and Biophysics, Univ of Washington School of Medicine, Seattle*

Previous studies, combining cortical ablation and determination of taste thresholds, suggested a cortical localization of taste near the somatosensory face area. This topographical relation has been further tested by mapping the cortical area electrically responsive to stimulation of the chorda tympani. This nerve, although conveying some tactile impulses from the tongue, primarily subserves taste. In cats under deep pentobarbital anesthesia, the lingual nerve was exposed from the tongue to the base of the skull, and divided central to its junction with the chorda tympani, which was left intact. The distal trunk containing the chorda tympani fibers was stimulated with single shocks, while the cortex of the same or opposite hemisphere was explored oscillographically for evoked electrical activity. Characteristic early response of the contralateral cortex was a sharp surface-positive wave (50–200 μV) of 10–12 msec latency. Ipsilateral responses were also obtained. Responses were irreversibly abolished by transtympanic destruction of the chorda tympani in the middle ear. The responsive zone, 4–5 mm² in area, was on the rostral orbital surface, superior to the rhinal fissure and anterior to the anterior ectosylvian fissure. It lay rostral and inferior to the tactile responsive zone for the face, and in its dorsocaudal extent, overlapped the latter. The remainder of the lateral and mesial surface of the cortex was unresponsive to chorda tympani stimulation. Insular cortex around the sylvian fissure, suggested by others as the cortical taste area, was consistently unresponsive.

Contribution to oximeter design using modulated light

W. PAUL (introduced by J. K. W. FERGUSON) *Dept of Pharmacology, Univ of Toronto, Toronto, Ont., Canada*

Using a flickering lamp and A-C amplification, the linear voltage-density characteristics of selenium photocells permit a new method of electrical compensation for varying opacity in the pinna of the ear. Our instrument has the usual two color channels, with an earpiece containing a pressure capsule and a lamp modulated at 125 c/s. The amplified alternating voltage for each channel is rectified and applied to a vacuum tube voltmeter. When the pinna is squeezed, a

positive bias is applied to the rectifier to adjust each channel to a 'zero' point without affecting the curve of output current against optical density. When blood is allowed to flow, compensation for varying Hb-density ('ear thickness') is applied by adjustment of a simple shunt control set according to the 'Infra Red' indication of Hb density. The calibration of this adjustment affords a convenient means of testing an earpiece design without recourse to arterial puncture. The earpiece is applied to the pinna of the ear of a fully oxygenated normal subject. After a preliminary warming period, pressure is applied to the pressure capsule and the bias controls adjusted to a 'zero' reading on both channels. Pressure is released and after Hb-density has become stable, the shunt control is turned to give a 100% reading on the saturation scale. Shunt control readings plotted against 'Infra Red' readings for a number of subjects provide an indication of the potential accuracy of the absolute saturation. Recent earpieces give a precision indicated by a range of $\pm 3\%$ saturation.

Oxygen partial pressures during hypothermia in the dog

K. E. PENROD *Dept of Physiology, Boston Univ School of Medicine, Boston, Mass*

The extent to which hypoxia occasioned by the considerable shift to the left of the hemoglobin dissociation curve is a contributory factor to death during hypothermia has been a subject of speculation since this concept was advanced by von Werz (*Arch f exper Path u Pharmacol* 202: 561, 1943). At 20° C rectal temperature the partial pressure of oxygen in mixed venous blood has been found to be of the order of 10 mm Hg, with a per cent saturation of 50 to 60. The fundamental question becomes: Is this low pressure sufficient to furnish adequate oxygen to the tissues when the metabolism is reduced by the cold? Answers to this question have been sought in several different ways centering about comparisons between dogs breathing air and those breathing 100% oxygen, inasmuch as in the latter case the physically dissolved oxygen is probably sufficient for the oxygen consumption at low body temperatures thus making hemoglobin dissociation largely unnecessary. Comparative oxygen consumption values, oxygen content of coronary sinus blood and of internal jugular blood are presented.

Method for analyzing the mechanical properties of smooth muscles stimulated by cooling JOHN F. PERKINS, JR. AND WILLIAM H. JOHNSON (introduced by A. B. LUCKHARDT) *Dept of Physiology, Univ of Chicago, Chicago, Ill*
Evidence was presented in a previous paper (PERKINS AND NICHOLAS, *Federation Proc* 8: 1949) that cooling causes contraction of smooth muscles

apparently by acting on a different excitatory system than epinephrine, or else acts directly on the contractile system. For this reason, studies of viscous-elastic properties of smooth muscles contracting *a)* under the influence of cooling, as contrasted with *b)* epinephrine or other drugs are being undertaken using the following method. A mechanically produced sinusoidal displacement is applied to a muscle through a spring. The displacements of the oscillator and of the muscle are detected electrically by the use of 2 transducer tubes, one applied through a glass stylus to the oscillator, and the other by the same method to the junction of the muscle and the spring. Each transducer tube gives a voltage output which is proportional to the mechanical displacement. This voltage is in each case amplified and converted to a current by D C amplifiers and cathode follower impedance changers, and the resulting currents are passed through 2 simple oscillographs which record directly on a kymograph drum. By this method, the amplitude and the phase relations between the 2 displacements can be obtained, and from this the viscosity and elasticity terms can be calculated before, during and at the height of contraction, and their frequency dependence also determined. Data obtained by this method will be presented.

A strain gauge amplifier for special biological application CLARENCE V PESTEL* AND JOHN P MARBARGER *Aeromedical and Physical Environment Lab, Univ of Illinois, Chicago*

A versatile instrument for amplifying the output of a strain gauge, such as the Statham, Model P23A or B, has been fabricated and tested. It is designed primarily for use in biological research where it is desired to record such pressures as arterial, venous, respiratory, etc. The instrument is of the carrier-frequency type, complete with a direct current output stage, capable of driving a rugged, high-speed, direct writing oscillograph. It is provided with a 5-position step-gain switch, together with a fine gain control, so that any pressure from a low value to maximum gauge pressure can be made to produce full scale deflection. Another 5-position switch on the instrument permits one to select *a)* zero position, so that any amplifier changes may be detected and corrected (by controls provided) without removing pressure from the strain gauge, *b)* calibration signal, so that a constant degree of amplification can be observed and reproduced, thus allowing one to establish comparable records from day to day, *c)* absolute pressure, *d)* mean pressure and *e)* pulse wave. The maximum sensitivity of the instrument is such that a pressure of 16 mm Hg applied to a Statham gauge, Model P23A, (0-750 mm Hg) will produce an output of 105 v across

3300 ohms. With the Statham gauge, P23B (0-50 mm Hg) much greater sensitivity can be attained. The output is linear with respect to the input until the output voltage exceeds 105 v.

Observations on reflex regulation of circulation

LYSLE H PETERSON (introduced by M E MAXFIELD) *Dept of Physiology, Univ of Pennsylvania Medical School, Philadelphia*

A number of surprising responses of the circulation following stimulation of various reflex systems have been observed in over 600 normal subjects and hospital patients during physiological experiments and surgery. Certain reflex responses appear to differ in man as compared with other species, to differ also with and without anesthesia. Following carotid sinus stimulation there appears to be a primary weakening of ventricular contraction concurrent with bradycardia. The effects are in contrast to those following prolonged diastole following premature or missed contractions. Following stimulation of the mesenteric receptors there also appears to be a primary weakening of contraction independent of pulse rate. Evidence is also presented to show that under various physiological, pathological and anesthetic conditions there is a marked alteration in the manner which the cardiovascular system reacts to changes within itself. This data is presented not only to demonstrate reflex circulatory phenomena in man (some for the first time) but also to stress the need for re-evaluation of present concepts of circulatory reflexes. Such generalizations which are commonly stated as Starling's and Marey's laws and the belief that the ventricles are not directly affected by the vagi must be thought of with reservation. An understanding of reflex balance in man seems necessary for an understanding of diseases of the cardiovascular system of man.

Regional distribution of blood flow after hemorrhage with and without Dibenamine RAYMOND W PICKERING (introduced by LANE H ALLEN) *Dept of Physiology, Univ of Georgia School of Medicine, Augusta*

Using flow meters of various types, the flows through the femoral artery, portal vein, carotid artery, inferior vena cava and hepatic veins have been measured during the course of a stepwise hemorrhage. Leg flow fell abruptly in mid hemorrhage, the resistance being markedly elevated. The high resistance was largely maintained until death. Venous O₂ content was reduced to a low value, and the O₂ consumption of the leg severely reduced. The vasoconstriction was largely prevented by pre-treatment of the dog with 5 mg/kg of Dibenamine. The visceral and carotid beds did not show this extreme resistance rise. As hemorrhage progressed, resistance showed minor eleva-

tion or held steady, and then declined progressively to low levels. Flow was reduced as cardiac output and arterial pressure fell. Hypoxia was less severe than in the legs. No significant differences between control and Dibenamine treated animals were found for either bed. The evidence indicates that vascular beds fall into two broad categories. In one, exemplified by the leg, centrally imposed vasoconstriction was not negated by tissue hypoxia. In the other, viz the viscera, brain, and presumably the heart, vasoconstriction is either absent, less active or is easily reversible by tissue hypoxia. Dibenamine lessens the difference between the two categories.

Extraction and fractionation of urinary corticosteroids GREGORY PINCUS AND LOUISE P. ROMANOFF * *Worcester Foundation for Exptl Biology, Shrewsbury, Mass and Tufts College Medical School, Dept of Physiology, Boston, Mass*

Normal human urine (24-hour sample) brought to pH 1 and extracted in a Hershberg type continuous extractor with CH_2Cl_2 for varying periods of time yields increasing amounts of neutral reducing lipid (NRL) and neutral formaldehydogenic steroid (FS). A maximal yield is had by 18 to 24 hours of extraction, with approximately 35% extractable at 4 hr and 55% at 8 hr. With extraction beyond 24 hr there is a falling off in the total amount. The absolute amounts recovered represent roughly a 4 to 5-fold increase over that extractable by hand extraction in the Heard-Sobel procedure. The neutral lipid extract may routinely be further fractionated by transfer to a silica gel (1-1.5 gm) column with 10-15 cc of benzene eluted by 10 to 30 cc amounts of organic solvents in the following order: a) benzene, b) benzene-ether mixtures, 2:1, 1:1 and 1:2, c) ethyl ether, d) ethyl ether-ethyl acetate mixtures 9:1, 4:1, 3:1, 2:1, 1:1, 1:2, e) ethyl acetate, f) acetone, g) methyl alcohol. b) tends to segregate the less polar steroids (e.g. 17-ketosteroids, 11-desoxycorticosterone-like substance) and c more polar steroids (e.g. corticosterone, 17-hydroxycorticosterone). Partition of the total neutral lipid between benzene and water results in a ratio of approximately 7:1 between fractions b) and c) in the benzene-soluble material whereas the ratio is 1:2 for the NRL and 1:5 for the FS of the aqueous phase. The chromatographed total neutral extract itself gives ratios of 2:1 for NRL and 1:2 for FS. Separation into ketonic and non-ketonic fractions does not alter the total neutral extract ratios markedly, but the presence of considerable non-ketonic corticosteroid is indicated.

Studies of epinephrine effect on portal circulation ELMER B. PRATT AND FRANCIS D. BURDICK (introduced by RICHARD WHITEHEAD) *Dept of Medicine, Univ of Colorado, Denver*

In unanesthetized dogs prepared either with London cannulae on portal and left hepatic veins or with duodenal cannulae for collection of bile, measurements were made of liver blood flow (constant bromsulfalein infusion method), plasma specific gravity, hematocrit, venous pressure and bile volume and specific gravity. The excellent condition of these animals has permitted their use in repeated experiments for more than 2 years. Injection of 0.1 mg of epinephrine hydrochloride into the femoral vein produced a typical cardiovascular response and elevation of the peripheral venous hematocrit. In simultaneous samples the hematocrit showed decreasing values from portal to hepatic to peripheral veins. There was a temporary elevation in plasma bromsulfalein concentration (30-40%) and a decrease (average 66%) in the dye concentration difference between portal and hepatic vein samples. The effect on bile flow and dye concentration was somewhat variable but the bile specific gravity was consistently decreased. The pressure was elevated in both portal and hepatic veins. The same dose of adrenaline injected directly into the portal vein produced no hematocrit, venous pressure, or general cardiovascular effects but gave the same type of bromsulfalein concentration changes. These results suggest that epinephrine acts directly on liver circulation to shunt blood flow away from the parenchymal cells.

New type of gradient calorimeter for rapid, simultaneous determination of heat loss and heat production in laboratory animals LAWRENCE R. PROUTY AND RICHARD W. LAWTON (introduced by McKEEN CATTELL) *Dept of Physiology, Cornell Univ Med College, New York City*

A gradient calorimeter of the Benzinger type, suitable for laboratory animals, has been built and tested. Its size is 32 x 24 x 18 inches. The half-inch thick Dural walls are lined with 2,152 copper-constantan strip thermal junctions wired in series. With an input of 21.6 Calories, 1,700 μv total output is obtained. This represents a drop of $1.85 \times 10^{-4}^\circ\text{C}$ across the gradient layer of 0.05 inch woven glass tape. Water vapor given off by the animal is condensed within a similar but smaller calorimeter unit (plate meter). Ingoing and outgoing air thermocouples measure heat loss to the circulating air. The calorimeter walls give a 100% response to direct radiation in 50 seconds, but the response time is slower with calorimeter contents in place. The thermal constant of the calorimeter is obtainable within ± 0.1 . The large mass of the calorimeter walls affords stability against minor rapid fluctuations in laboratory temperature. Heat production is determined from oxygen consumption, as measured by a Pauling

oxygen meter, and carbon dioxide production, as measured by an infrared gas analyzer. Both direct and indirect calorimetry, rectal and skin temperatures are simultaneously recorded by a Leeds and Northrup eight-point recorder. The calorimeter and associated equipment have the following advantages, a) rapid response to changes in heat production and heat loss, b) furnishing either a stable or rapidly changing thermal environment for the animal subject, c) a simple measurement of vaporization, and d) continuous recording of all measurements. The calorimeter should make possible critical experiments on thermoregulatory mechanisms of animals.

Spread of excitation process in ventricular myocardium of dogs RAYMOND D. FRUITT (introduced by NORMAN M. KEITH) *Mayo Clinic, Rochester, Minn.*

Two series of experiments were carried out. In one, direct-lead electrocardiograms were recorded from the ventricular cavities and epicardial surfaces of isolated, perfused canine hearts, into the cavities of which caustic solutions were introduced. In the second, electrocardiograms of a similar type were recorded from strips of the myocardium which retained attachment to the ventricle at only one end. The following conclusions have been reached. First, if rapid transmission of the excitation process through the endocardial tissues is a function of a specialized tissue (the Purkinje system), destruction of that tissue has not been accomplished. Second, in view of the severity of trauma effected by the agents introduced into the ventricular cavities, escape of such specialized tissue from injury seems unlikely. Third, muscle-strip experiments lend support to the concept that variation in speed of transmission of the excitation process may be related not to differences in the nature of the tissues, but rather to peculiarities in their arrangement. Excitation moves rapidly along a strip composed of longitudinally disposed fibers, and slowly down a strip made up of fibers arranged in a transverse manner.

Accurate registration of intralumen pressures of the digestive tract by two new methods J. P. QUIGLEY, DANIEL A. BRODY,* BILLY MCKAY,* W. C. LANDOLINA* AND J. H. MCALISTER* *Dept. of Physiology, Univ. of Tennessee, Memphis*

Pressures within the lumen of the canine digestive tract have recently been accurately recorded by two new methods. 1) An improved form of the pressure-conduction method of Brody and Quigley (*Gastroenterology* 9: 570, 1949) transmits pressure from a moderately soft plastic tip (3 x 8 mm) within the gut through 0.4 mm bore plastic tubing to a Sanborn electromanometer. The pos-

sibility of tube plugging is minimized by the slow flow (5 cc/hr) of clean, dry gas through the tubing. Lengths of tubing up to 100 cm. are feasible when helium is substituted for air as the conducting medium. The electromanometer permits registration by either optical or direct-writing methods and the sensitivity can be varied at will. 2) A newly developed electromagnetic transducer consists of a 3 x 20 mm transducer placed in the cavity from which pressure is to be measured. This transducer has a self-supporting, center-tipped coil which forms two arms of a balanced induction bridge. Changes in intralumen pressures of the gut cause proportional displacements of an elastically mounted iron core. The apparatus is so calibrated that the resulting electrical imbalance is recorded in terms of pressure. The volume/pressure coefficient of this device is exceedingly small and plugging cannot occur. Pressure observations made by these two methods closely resemble in magnitude and in general form the results we previously obtained by our less refined methods and appear to confirm the validity of these earlier observations.

Simultaneous determination of bloodflow through each lung H. RAHN AND H. T. BAHNSON* *Dept. of Physiology and Vital Economics, Univ. of Rochester School of Medicine and Dentistry, Rochester, N. Y.*

If the gas content of the arterial blood, the R.Q. and metabolic exchange rates can be determined for each lung separately, it is possible to calculate the mixed venous point and consequently the blood flow through each lung by the Fick principle. This is true only if the arterial gas contents of the two lungs differ. By means of a differential bronchial catheter, alveolar air was recorded continuously and simultaneously from each lung. The gas content of the arterial blood was determined from the alveolar air tensions and the blood gas dissociation curves. The R.Q. can be ascertained from either the alveolar air or the expired air determinations. In order to calculate the gas content of the mixed venous blood, the arterial point for each lung is plotted on a diagram having O_2 and CO_2 blood gas contents as ordinates. Through each of these arterial points a straight line is drawn which has a slope that depends on the R.Q. for that lung. The point of intersection of these lines represents the composition of mixed venous blood which is the same for each lung. In nembutalized dogs breathing air, approximately 45% of the total circulation perfuses the left lung. This fraction is reduced to approximately 25% within 10 minutes after the administration of nitrogen to the left lung only. No further significant changes were observed at the end of one hour of nitrogen exposure. This

vasomotor reflex actually occurs within 1-3 minutes as shown by qualitative measurements employing the rapid infra-red gas analyzer

Species variability in the inactivation of penicillins

G and K NATHAN RAKIETEN, GEORGE VALLEY* AND EDNA W LYON * *Bristol Labs Inc, Syracuse, N Y*

It is necessary to administer per unit body weight a larger total amount of penicillin (repository forms) to a rat than to a rabbit or dog to obtain a measurable blood level for 24 hours. Further, penicillin G, when administered i m to mice in aqueous solution, disappears from the blood more rapidly than it does in rabbits (EAGLE *et al J Bact* 57 122, 1949). In studying the factors which might play a role in the inactivation of pure penicillins G and K *in vivo* and *in vitro* a species difference was noted between the rat and rabbit. In the intact rabbit K disappears from the blood more rapidly than G following i v administration. This is also true in the renal-ligated (R L) rabbit. In contrast in the eviscerated renal-ligated (E R L) rabbit the blood levels obtained after i v administration of K approach those obtained with G after equilibration has occurred. The rat differs from the rabbit in that in the R L animals, and apparently in the intact also, G and K disappear from the blood within the same time intervals. However in the E R L rat both G and K remain in the blood stream at constant levels for at least 3 hours. *In vitro* studies using the Warburg apparatus failed to show any marked differences between rabbit and rat liver slices. Neither inactivated G and both inactivated K. Apparently some mechanism is present in the liver of the intact and R L rat which allows for the inactivation of G as well as K.

Estrogen content of blood of ovarian vein of the dog and spermatic vein of the stallion

A E RAKOFF* AND A CANTAROW *Division of Endocrine and Cancer Research, Jefferson Med College, Philadelphia, Penna*

As part of an investigation of the rate of secretion of hormones by certain endocrine glands, the quantity of estrogen was determined, by bioassay, in blood collected from 1) the ovarian vein of dogs after gonadotrophic stimulation, 2) the spermatic vein of stallions and 3) a peripheral vein. After ovarian stimulation with pregnant mare serum gonadotrophin for 8 to 10 days very little estrogen (10 mouse units/100 cc of serum or less) could be found in blood collected at operation from the ovarian veins of 4 dogs, thus suggesting a relatively slow secretion of small amounts of estrogens. Blood collected from the spermatic vein of 2 stallions showed very high serum estrogen values (264 and 100 MU/100 cc respectively), which were many times greater than those for

peripheral venous blood (20 MU/100 cc) determined simultaneously, indicating a relatively rapid secretion of large amounts of hormone from the testis. The estrogens in the spermatic vein blood were entirely in 'free' form, in the peripheral blood, approximately half of the estrogen was 'protein-bound' in one instance and entirely in the free form in the other.

Functional analysis of the vasomotor innervation of the dog's footpad

W C RANDALL, W F ALEXANDER,* J W COX* AND A B HERTZMAN *Depts of Physiology and Anatomy, St Louis Univ School of Medicine, St Louis, Mo*

During faradic stimulation of the sympathetic chain, vasomotor responses were recorded by the photoelectric plethysmograph from the hind feet of the anesthetized dog. Extensive variations in the position of ganglion swellings required specific reference to precise vertebral levels in localizing ganglia on the sympathetic chain. Although apparent fusion of right and left chains caudally was commonly observed, little evidence of contralateral response to stimulation was noted. Post-ganglionic vasomotor outflow from the ganglion chain to the footpad was determined by stimulation of individual ganglia after section of the chain both superior and inferior to the point of stimulation. Although some variation was observed, the largest postganglionic supply to the footpad was shown to be derived from ganglia at vertebral levels L₆ to S₁. The inflow of preganglionic vasomotor fibers innervating the footpad was determined by recording vascular responses during direct stimulation at successively lower levels on the chain. As additional preganglionic fibers enter caudally, vasoconstriction in the foot became more intense. Individual oblique rami were stimulated wherever possible. Very few vasomotor preganglionic fibers to the footpad were found to enter the chain above the vertebral level L₄, and the maximum inflow appears to be between L₄ and L₆.

Effects of adenine ingestion in the dog

SIGWIN B RASKA *Dept of Physiology and Pharmacology, Univ of North Dakota School of Medicine, Grand Forks*

Oral administration of adenine to dogs in daily doses of 50 to 100 mg/kg produces, within one or two weeks, hemorrhage and/or ulceration of buccal mucosa, gums and ventral surface of tongue. These lesions are usually bilateral and symmetrical. These lesions can be cured or prevented by intramuscular injection of penicillin. The tongue of these dogs often becomes atrophic and necrotic. Mucosal and submucosal hemorrhages are always present. Applied pressure to mucosal membrane results in profuse bleeding. The hemorrhagic tendency resembles that of vitamin K deficiency.

The hemorrhages of the gums especially around the teeth simulate those seen in experimental vitamin C deficiency. Indications for CNS disturbances were a waddling gait with muscular asthenia of the hind parts and clonic convulsions, especially in the pelvic and shoulder girdles. In the late stages there was peripheral anesthesia. The cornea became opaque and the sclera and conjunctiva very inflamed. Vision appeared decreased. In addition to previously described autopsy findings (RASKA, S. B. *Science* 105, 2718, 1947, *Federation Proc* 8 130, 1949) the following was noted: diffuse patchy hemorrhages in both lungs; hemorrhages of myocardium, especially of the auricle and of the ventricle at the auriculo-ventricular junction; section of the heart muscle showed multiple small hemorrhagic foci and in one of the heart muscle sections accumulation of cells suggestive of Aschoff Bodies, congestion of gastric mucosa with extensive hemorrhages in mucosa and submucosa. Scattered patchy hemorrhages and congestion in lower jejunum, ileum, and in the mucosal folds of the sigmoid, pancreas and adrenals showed hemorrhagic foci. Peri-adrenal hemorrhages also were found. Much of the syndrome produced by adenine simulates clinically as well as microscopically the syndrome exhibited by animals suffering from multiple avitaminosis.

Nitrogen retention produced by adenine SIGWIN B. RASKA *Dept of Physiology and Pharmacology, Univ of North Dakota School of Medicine, Grand Forks*

A marked increase of N P N, urea, uric acid and creatinine in the blood follows, within one or two weeks, the oral or parenteral administration of 30-50 mg/kg of adenine to dogs receiving a complete normal diet before and during the experimental period (RASKA, S. B. *Science* 105 1947, *J Biol Chem* 165 743, 1946, *Federation Proc* 8 130, 1949). A definite relationship exists between the degree of nitrogen retention and the dosage and duration of adenine administration. A decrease in the daily dosage causes a less pronounced nitrogen retention and discontinuation causes a gradual lowering of the nitrogen retention. The maximum nitrogen retention in mg % ranged N P N, 160 to 260, urea, 100 to 200, uric acid, 3 to 8, creatinine, 4 to 10. Creatinuria was often present. As previously reported parenchymatous degeneration of the kidneys was found at autopsy. Similar blood and autopsy findings as reported for dogs were also present in rats. Larger daily doses of adenine (e.g. 100 mg/kg) produces in dogs, within one or two weeks, mucosal and submucosal hemorrhages, ulceration of buccal mucosa and tongue, conjunctivitis, scleritis, opaqueness of cornea, dermatitis and tremors of the skeletal muscles. Many of the lesions are simi-

lar to those described for experimental multiple avitaminosis. These lesions can be cured or prevented by intramuscular injection of penicillin. Administration of adenine to animals would seem to provide a means for producing experimental uremia. The possibility exists that a prolonged increased concentration of adenine or its metabolic products in the blood and tissues due to a faulty nucleoprotein or purine metabolism might play an important role in pathologic states, especially those associated with nitrogen retention and kidney diseases.

Comparison of procaine and tridiurecaine G. CARL RAU* AND B. A. WESTFALL *Dept of Physiology and Pharmacology, Univ of Missouri Med School, Columbia*

A comparison of the toxicity, general analgesia and degree of local anesthesia produced by a new compound, tridiurecaine hydrochloride (a procaine substituted diurethan), with procaine hydrochloride in rats and dogs has been made. The LD₅₀ values (intraperitoneal injection) of tridiurecaine and procaine were found to be approximately equal in rats. Unanesthetized dogs injected intravenously with tridiurecaine (1 mg/kg/5 min) showed a degree of general analgesia as great as dogs receiving equal doses of procaine. Over dosage of tridiurecaine in both rats and dogs produced mild sedation followed by respiratory paralysis and death instead of excitation, convulsions and death, characteristic of procaine. The anesthetic potency of tridiurecaine injected intradermally (0.2 cc of 1% solution per wheal) in dogs was approximately the same as the anesthetic potency of procaine (0.2 cc of 1% per wheal). Intravenous injection of tridiurecaine (1 mg/kg) into dogs anesthetized with pentobarbital sodium produced a small rise in blood pressure. Larger dosage (3 mg/kg) did not alter blood pressure significantly, but inhibited respiration, but about 5 mg/kg produced respiratory paralysis followed by a gradual circulatory failure and eventual death due to the respiratory difficulty.

Effects of ACTH on synovial membrane potentials in rheumatoid arthritis C. I. REED, NORMAN R. JOSEPH, IRVING E. STECK,* AND M. M. MONTGOMERY* *Univ of Illinois, Chicago Professional Colleges, Chicago*

In work previously published a method has been described for determining the potential difference between the inner surface of the synovial membrane and a subcutaneous reference junction in anesthetized dogs. Also a tentative interpretation of results has been presented. This technic has been modified and adapted for similar studies on intact, unanesthetized human subjects.

with uncomplicated rheumatoid arthritis, and also on healthy control human subjects. The reference junction was applied to the skin. In the normals, the resting potential ranged from 0 to +5 mv. Patients with rheumatoid arthritis showed potentials of the order of 20 to 60 mv positive at the joint. Intramuscular injection of 25 mg of ACTH in all cases so far studied caused a sharp reduction within 5 to 20 minutes, sometimes by 50%, sometimes to the normal range. Further treatment on a schedule of 25 mg every 6 hours invariably reduced the potential to near zero. After 12 doses, placebos were substituted. An upward trend of positive potential was apparent usually within 3 to 4 days, in general correlated with return of subjective symptoms and limitation of mobility.

Directional effect of electric current on secretion of chloride ions by the dog's stomach WARREN S. REHM, *Dept of Physiology, Univ of Louisville, Louisville, Ky*

Previous results have demonstrated that the production of H^+ ions by the secreting stomach can be controlled by the directional application of current (*Am J Physiol* 144:115, 1945). On the basis of these and other findings a theory of HCl production was formulated (*Gastroenterology*, In press). Analysis of this theory leads to the prediction that the effect of current application on Cl^- ion production should be in the opposite direction to its effect on H^+ ion production. Experiments were performed to test this prediction. The technique described in the above reference was used. An isotonic $NaNO_3$ solution made contact with the mucosal side and was replaced at definite intervals. The Cl^- ion and H^+ ion content of this fluid was determined. It was found (5 dogs) that from 6-26 microequivalents of Cl^- ion/gm dry weight of stomach/10 min was secreted by the resting stomach. Application of current from serosa to mucosa resulted in a decrease in the Cl^- ion secretion of the resting stomach, and application of current in the opposite direction resulted in an increase. In the secreting stomach the above prediction was borne out since it was found that current sent from serosa to mucosa resulted in an increase in the secretion of H^+ ions and in a decrease in the secretion of Cl^- ions, and also that application of current in the opposite direction resulted in a decrease in H^+ ion secretion and an increased Cl^- ion secretion.

Skeletal muscle as a source of plasma potassium during the removal of potassium by vivodialysis ROGER M. REINECKE AND FRANCIS L. STUTZMAN, **Dept of Physiology, Univ of Minnesota, Minneapolis*

A skeletal muscle, the gastrocnemius or the

cranial part of the sartorius, was isolated except for its blood and nerve supply in a dog anesthetized with sodium pentobarbital. The plasma potassium level was then reduced by vivodialysis (*Am J Physiol* 157:401, 1949). Under these circumstances there was an arteriovenous increase in the plasma potassium concentration of blood flowing through the muscle.

Relation between stroke index and time of diastole in the intact dog JOHN W. REMINGTON, *Dept of Physiology, Univ of Georgia School of Medicine, Augusta*

For a dog showing sinus arrhythmia, the stroke indexes of 86 consecutive pulses were plotted against the time of previous diastole. The points describe a definite curve, with standard deviation of $\pm 10\%$, 240 pulses taken from newly anesthetized dogs before and after vagotomy or atropinization show a similar curve, with S.D. $\pm 15\%$. Both curves show a linear relation from diastolic lengths (T_d) of 1200 to 700 msec, a curvature toward reduced stroke indexes from 700-300, and stroke indexes scattering about a fairly constant minimal T_d value of 160-200. Pulses taken from dogs after hemorrhage follow an almost parallel curve but at lower stroke index values. A curve taken at the height of an epinephrine pressor response shows sub-normal stroke indexes, with greater discrepancy at high T_d values than at low. All curves show maximum cardiac output at heart rates of 130-170. Stroke indexes calculated from the carotid pulse records of Y. Henderson (*Am J Physiol* 23:345, 1909) agree with his cardiometer volumes within an ave. of $\pm 12.5\%$. Neither set of data seem to support his setting 210 as the optimum heart rate. A major part of the flow decline seen in late hemorrhage seems referable to the fast heart rate, which is congruent with the small heart volume and rising venous pressure found at this time.

Renal tubular excretory mass and reabsorption of sodium, potassium and chloride in testosterone-treated and estradiol-treated female dogs J. A. RICHARDSON* AND C. R. HOUCK, *Dept of Pharmacology, Medical College of South Carolina, Charleston, and the Dept of Physiology, Univ of Tennessee, Memphis*

The effects of various doses of testosterone propionate and of alpha-estradiol benzoate on the renal tubular reabsorption of sodium, chloride and potassium and the tubular excretory mass (TmPAH) in normal female dogs have been studied. Testosterone propionate in 10 to 12 daily intramuscular doses of 3, 6, and 10 mg/kg had no significant effect on TmPAH, or on the tubular reabsorption of sodium, chloride and potassium. In animals receiving alpha-estradiol benzoate in sufficient, daily, intramuscular doses to produce

estrus in approximately 10 days (daily doses of 80-2000 rat units/kg) glomerular filtration rate was unchanged or reduced for varying periods after the injections. Whereas the tubular reabsorption mechanisms for sodium and chloride remained normal, the percentage of filtered potassium reabsorbed decreased as much as 50% during a variable time following estrogen administration. A return to normal occurred over a period of several weeks. In untreated as well as treated animals, the tubular reabsorption of sodium and chloride bore a directly proportional relationship to filtration rate. In the estradiol-treated dogs, TmPAH was moderately to markedly reduced (15-50%) over a period of several weeks following administration of the estrogen, probably as a result of a non-specific depression of the enzymes that control PAH transport. A gradual return to normal occurred during a recovery period of several weeks. With both testosterone propionate and estradiol benzoate no significant changes were noted in the microscopic structure of the kidney or in the kidney weight/body weight ratio.

Changes in hemoglobin during metamorphosis in the bullfrog (*Rana catesbeiana*) AUSTEN F. RIGGS, II (introduced by GEORGE WALD) *Biological Labs, Harvard Univ, Cambridge, Mass*

McCutcheon has reported that tadpole hemoglobin has an affinity for oxygen several times greater than that of the adult bullfrog, and that during metamorphosis the oxygen equilibrium function also changes in shape from a hyperbola to sigmoid—i.e., the value of n in Hill's equation increases from 1-2 (*J Cell & Comp Physiol*, 8: 63, 1936). This could indicate either that 1) tadpole hemoglobin possesses only one heme, and has perhaps a small molecular weight like that of myoglobin, or 2) it is of normal constitution, but its hemes do not interact. Examination of tadpole hemoglobin in the ultracentrifuge, with the cooperation of Prof. J. L. Oncley, shows that its molecular weight is like that of other vertebrate hemoglobins. Its sedimentation constant, s_{20} , when extrapolated to zero concentration, is about 4.9. With new techniques developed in cooperation with Prof. J. Wyman, the oxygen equilibrium function has been remeasured accurately in bullfrog tadpoles and adults. The function is sigmoid in both instances, the value of n in Hill's equation does not appear to change with metamorphosis. McCutcheon's observation that the oxygen affinity increases greatly during metamorphosis, however, is confirmed. These relationships are being explored further.

Mapping electrokymographic responses over the cardiac silhouette GORDON C. RING, A. SOKALCHUK* AND G. J. NAVIS*

The electrokymographic (EKY) records of x-ray density changes of the heart in general show

thinning during ejection and thickening during filling. Often, however, thinning is indicated during a portion of the filling period and thickening during a part of ejection. These paradoxical effects must be due to changes in position of the heart—a thinner portion of the heart moving into the x-ray beam during diastole and a thicker portion moving in during systole. In order to gain a better understanding of these effects, the EKY responses over each square centimeter of the cardiac silhouette have been carefully mapped. With the dog lying on his right side, EKY records from the sternal side of the heart show a peak which occurs after ejection begins. As one moves toward the spinal side of the silhouette these peaks appear earlier in systole and the amplitude of the responses increases. These changes in pattern can be explained by the changes in position of the dog's heart.

Analysis of value 'K' in Bazett's formula JANE S. ROBB

Dept of Pharmacology, Univ of Syracuse College of Medicine, Syracuse, N. Y.

All investigators find that the duration of electrical systole (QT) varies with cycle duration. The average value of 'K' is 0.37 for normal men. If one calculates K for the values of QT tabulated by Ashman and Hull for normal men, K does not prove to be 0.37 for all cycle lengths. If K values are again related to cycle, a smooth curve results. Experimentally, it is possible to keep cycle almost constant and to alter K. When K is calculated for 533 athletes and for 250 presumably normal medical students, graphs relating K to cycle do not overlap. Moreover, if the athletes are classified according to their major sport, certain sports seem to have a greater effect on K than do others. These facts make one doubt that the QT/cycle relationship is simply that of one dependent and one independent variable. To imply that 'K' represents 'QT corrected for cycle duration' is misleading. An alternate explanation is that some phase of cellular activity determines both QT and heart rate, that both are often changed proportionately thus producing an apparent rather than a real relationship. K seems to be a very sensitive indicator of the 'state of the heart muscle' as was suggested for QT by Blair, Wedd and Young; nevertheless its full significance is elusive. For instance, is an athlete's heart whose K is lower, better or worse than the heart of a medical student who has a higher K at the same cycle duration?

Blood vessels of nerves, as seen in living animals with quartz rod illumination and their response to drugs including cortisone JOSEPH T. ROBERTS, H. R. MURDOCK, JR.,* J. L. CAMPO,*

C. J. TANNER,* AND J. A. PAPARELLA.* *V. A. Hospital, Batavia, and Univ of Buffalo School of Medicine, Buffalo, N. Y.*

Vessels in small and large nerves of frogs and

small mammals, *in situ*, change calibre and flow volume in response to drugs, stimulation with electrodes, shock, stretching, compression and other states. Observations were made during life with the quartz rod apparatus. Rhythmical contractions, especially of arterioles of larger size, were seen. Large fusiform dilatations (sinusoids) of transverse branches were seen often in vasa nervorum of rabbits, these may serve as regulatory shunts to control vascularity of nerves. Constriction of vessels in nerves followed injection or application of epinephrine, or electrical stimulation of the nerve's field. Dilatation of these vessels followed injection of histamine or inhalation of amyl nitrite. Other drugs, including cortisone, and other procedures are being evaluated as to their effects upon the vasa nervorum, using somatic and visceral nerves and ganglions. Sludging of blood has been observed in the vasa nervorum (as noted by Knisely and others), and efforts to correlate this with systemic or generalized sludging as well as neural functions are being made. The vasa nervorum are rather abundant throughout the thickness of each nerve and are believed to have a significant role in the function of the nerve, as shown in earlier experimental and clinical studies. The occurrence of spasm and dilation of the vasa nervorum observed here supports the hypothesis of a reflex arc (proposed by Roberts, 1948) which produces 'referred pain' by ischemia of the somatic nerves in the areas of referred pain when a stimulus arises in a visceral organ associated centrally with these nerves. 'Trigger areas' in somatic nerves may be due to ischemia of the nerve due to spasm, infarction or other vascular lesions within the nerve.

Permeability of *Escherichia coli* R. B. ROBERTS AND R. T. NIESET (introduced by S. R. M. REYNOLDS) *Carnegie Inst of Washington, Dept of Terrestrial Magnetism, Washington, D. C. and Tulane Univ., New Orleans, La.*

Measurements of the permeability of cells of *E. coli* to ions of sodium and potassium have been reported (COWIE, D. B., R. B. ROBERTS AND I. Z. ROBERTS *J. Cell & Comp. Phys.* October, 1949). Using the same methods we have extended these observations to ions of rubidium, caesium, cobalt, phosphate, sulfate, and sulfide. In all cases permeability was found to be high. The ionic concentration of the cells was found to be at least 75% of the concentration in the medium, reaching equilibrium in less than 5 minutes under conditions of low metabolic activity. It appears that 75% of the cell volume is 'water-space' and that ions are freely exchanged between this water space and the external medium. In the presence of high metabolic activity enormous concentrations of the ions in the cell are observed, although the amount in the water space remains about con-

stant. A high permeability was also found in other cells which are reported to show effects of osmotic pressure.

Body fluid redistribution in induced hypothermia and hyperthermia S. ROBBARD, HIROSHI SAIKI* AND ARTHUR MALIN* *Cardiovascular Dept., Medical Research Inst., Michael Reese Hospital, Chicago, Ill.*

Numerous studies have suggested that hemodilution occurs in hyperthermia, and hemoconcentration occurs in hypothermia, but these deductions have been inferred from changes in the osmotic pressure or the plasma protein concentration of the blood. No data are available, as far as we are aware, on the actual changes in the blood volume and its relation to changes in the extracellular and intracellular fluid compartments. Our studies on physiological effects induced by changes in body temperature were therefore extended to investigate possible fluid shifts between these volumes, in order to assay more adequately the effect on the cardiovascular system. Rabbits and chicks were used. Lowering the body temperature to 25°C resulted in only a slight increase in hematocrit and specific gravity. However, plasma and blood volumes and thiocyanate space were all reduced 30% below normal levels. Rewarming resulted in a return to normal values. Induced hyperthermia resulted in a slight decrease in hematocrit and in plasma specific gravity, plasma and blood volumes were slightly reduced, but thiocyanate space was increased as much as 30%. These data suggest that induction of hypothermia results in a marked shift of fluid from the plasma and the interstitial spaces to the intracellular phase. The fact that the hematocrit and specific gravity do not rise commensurate with the decreased volumes suggests that blood cells and plasma proteins are removed from the circulating plasma and stored. The reverse processes are brought about by rewarming to normal temperature levels. Induction of hyperthermia causes water to leave the tissue cells, and causes commensurate quantities of plasma protein and blood cells to be released to the circulating blood stream.

Cardiodynamic effects of shunts from the great arteries to the auricles S. ROBBARD, S. KRAUSE,* R. REYNOLDS,* M. LOWENTHAL* AND J. SCHACK* *Cardiovascular Dept., Medical Research Inst., Michael Reese Hospital, Chicago, Ill.*

Cardiodynamic effects of surgically produced shunts connecting either the pulmonary artery or the aorta to either of the auricles have been studied in acute and chronic preparations. The effects of a connection between the pulmonary artery and the right auricle have already been reported. Anastomosis in acute experiments of the pulmonary artery to the left auricle, with a flow

through the shunt of 500 cc/min, results in reduction in the oxygen saturation of the systemic arterial blood, the right auricular pressure remains unchanged, the pulmonary arterial systolic pressure increases while the pulmonary diastolic falls resulting in an increase in pulmonary pulse pressure, the left auricular pressure rises and the central aortic pressure remains unchanged. In chronic experiments a calculated shunt of 50% of the cardiac output has been maintained as long as 3 months. Anastomosis of the subclavian artery to the left auricular appendage with flows through the shunt of as much as 3 l/min produced little changes in the right auricular or pulmonary arterial pressures, the left auricular pressure increased and the central aortic pulse pressure increased markedly. These experiments demonstrate that the heart can accommodate to enormously increased input loads without signs of dilatation or failure provided the insult is not placed too suddenly. Sudden overloading with even relatively small amounts of shunted blood led to dilatation and failure, while gradual increase of the input load permitted adaptation to inputs which at least doubled the cardiac output.

Muscle potentials in various insects during flight

KENNETH D ROEDER *Dept of Biology, Tufts College, Medford, Mass*

Pringle (*J Physiol* 108: 226) has shown that potentials (5–10 mv) recorded from the thoracic muscles of flies occur at a lower frequency than the wing movements. He suggests that the indirect flight muscles constitute a resonant system in which the contraction of one muscle group is the direct result of mechanical stretch caused by contraction of the antagonists. Periodic excitation of nervous origin serves to initiate contraction and to maintain the system in a state where it is capable of oscillation. Intrathoracic potentials and thoracic vibrations have been recorded simultaneously in various insects during stationary flight. In the cockroach (*Periplaneta*) and a moth (*Agrotis*) with wing rates of 20–40 per second one muscle potential occurs during each wing cycle, and there is at present no evidence that each excitation of the wing muscles is not of nervous origin. In a wasp (*Vespa*) and in flies (*Lucilia*, *Calliphora*, *Tabanus*) with wing rates of 120–180 per second there may be 4–15 wing cycles to each intrathoracic potential. Removal of the wing load may double the wing rate and decrease the potential frequency so that the ratio may become as high as 40:1. This suggests nervous feedback determined by the amplitude of the oscillation. Spontaneous termination of flight in these forms is usually signalled by cessation of potentials followed by a gradual decline in vibration amplitude with little or no change in vibration

frequency. It is concluded that generalized slow-flying insects have a conventional mechanism of muscle excitation, while specialized insects with high wing rates show the novel excitatory mechanism described by Pringle.

Neuromuscular excitation in the cockroach

KENNETH D ROEDER AND ELIZABETH A WEIANT * *Dept of Biology, Tufts College, Medford, Mass*

Electrical and mechanical changes following indirect excitation of one of the tergo-trochantal muscles of the cockroach, *Periplaneta americana*, were recorded from electrodes and a piezo-electric stylus placed on the exposed muscle surface. The electrical sign of muscle excitation is a positive potential of 4–5 msec duration, which begins 1.2 msec after the arrival of the nerve action potential at a point where the motor nerve penetrates the muscle substance. Contraction begins 3.0 msec after the onset of the muscle potential. The preparation behaves as a single motor unit, neither electrical nor mechanical response being subject to facilitation or gradation. Contractions begin to fuse at stimulus rates above 40–50 per second, which is well above the wing rate (25–30 per second) for this insect during flight. The muscle potential elicited by the second of a pair of liminal stimuli can be detected until the stimulus interval is less than 2.0 msec, though it becomes progressively smaller as the stimulus interval is reduced from 20 msec. Neuromuscular transmission is unaffected by curare, though the muscle becomes completely inexcitable 3–5 days after surgical transection of the motor nerve. It is concluded that conduction in this muscle depends entirely upon many branches of a single motor nerve fiber, the muscle potential being the sum of local potentials developed simultaneously in several muscle fibers, and in sequence at many motor endings on each muscle fiber. The potential change during activity of cockroach muscle appears to be similar to the end-plate potential of vertebrate muscle.

Recovery of glomerular and tubular function, including p-aminohippurate extraction, following two hours of renal artery occlusion in the dog

BETTY S ROOF,* HENRY D LAUSON, S THEODORE BELLA* AND HOWARD A EDER * *Hospital of Rockefeller Inst for Med Research, New York City*
Hamilton, Phillips and Hiller (*Am J Physiol* 152: 517, 1948) produced severe but reversible kidney damage in dogs by 2 hours of renal artery occlusion. Urea clearance returned to normal in about 35 days. The present study extends this observation to include clearances of creatinine (Cr) and p-aminohippurate (CPAH) and TMPH

in 3 dogs. In dogs 2 and 3, with single explanted kidney, measurement of PAH extraction permitted calculation of actual plasma flow (RPF). Within 1 hour after clamp release, clearances measured 2, 10 and 26% of control in dogs 1, 2 and 3, respectively. Recovery thereafter proceeded as follows. Dog 1 Progressive improvement in all functions began immediately. $CPAH$ reached 89% of control by the 35th day, $TPAH$ reached 90% only by the 78th day, with CCr and C_{urea} still under 70%. Dog 2 RPF was above normal for 1 week and moderately subnormal afterwards. Clearances varied around 20% and rose only after the 11th day. PAH extraction reached 89% of control on the 23rd day, but by the 32nd day, CCr , $CPAH$ and $TPAH$ measured only 30, 42 and 48%. Dog 3 Showing least initial impairment, CCr , $CPAH$ and $TPAH$ all reached about 60% by the 26th day with RPF slightly subnormal throughout. PAH extraction was normal by the 15th day. In all 3 dogs, $CCr/CPAH$ decreased slightly. The data indicate that the decreased clearances and $TPAH$ during the first weeks after 2-hour clamping are due mainly to factors other than concomitant reduction of RPF.

Effect of thiocarbonamide derivatives in alloxan diabetes I N ROSENBERG AND M S RABEN (introduced by E B ASTWOOD) *New England Center Hospital and the Dept of Medicine, Tufts Med School, Boston, Mass*

A curative action of thiouracil in mild alloxan diabetes has been reported by Houssay and Martinez (*Rev Soc argent de biol* 24 63, 1948). In the present study, observations were made on the effect of a variety of thiocarbonamide and other sulfur compounds on the daily weight, food and water consumption, urine volume and glycosuria of moderately and severely alloxan diabetic rats. The test substances were administered admixed with the food for periods of 3 to 19 days. Parallel experiments were performed on a similar group of diabetic animals which received, in addition to the test compounds, a constant daily suboptimal dose of insulin. Thiourea, 1,1,3-trimethylthiourea, 6-*n*-propylthiouracil, 6-cyclopropylthiouracil, 6-*tert* butylthiouracil, 6-*isobutyl*-thiouracil, 6-trifluoromethylthiouracil, 6-carboxy-thiouracil, dihydrothiouracil, 2-mercaptoimidazole, 2-mercaptothiazole, 5,5-dimethyl-2-mercaptothiazoline, 5,5-dimethyl-2-thiothiazolidone, 5-vinyl-2-thiothiazolidone, 3-phenyl-2-thiothiazolidone, 2-mercaptobenzimidazole, 4-phenylthiosemicarbazide, tetramethylthiuramdisulfide, tetraethylthiuramdisulfide, 5,5-diethylthiobarbituric acid, 5,5-diethyl 2,4,6-trithiobarbituric acid, tetrahydro-2-thiopyrimidone, methylene blue, cysteine, and cystine were tested. When judged on the ability to produce an insulin-like

effect of diminution of glycosuria associated with weight gain, none of the substances was found to be of intrinsic benefit in either group of animals. The decreased glycosuria, polyuria and food consumption observed in some animals were coincident with weight loss, and interpreted as toxic effects of the substance administered, prolonged treatment with those substances which have antithyroid effect sometimes induced similar changes, possibly due to myxedema. Food restriction alone diminished glycosuria and caused weight loss proportional to the degree of reduction in food consumption. It is concluded that the substances investigated neither improve carbohydrate tolerance nor enhance insulin-sensitivity of diabetic rats under these conditions.

Effect of temperature-change upon round window response in hamster and bat WALTER A ROSENBLITH,* LAWRENCE KAHANA,* AND ROBERT GALAMBOS *Psycho-Acoustic Lab, Harvard Univ, Cambridge, Mass*

The body temperature of hamsters and bats under barbiturate anesthesia was reduced in a manner simulating their normal hibernation. The electrical response to acoustic clicks was recorded from the round window over the ranges 40°-18° C (hamster) and 30°-8° C (bat). At ordinary temperatures the round window response resembles in all important respects that recorded from the cat and the guinea pig. Microphonic and neural components are readily distinguished. The essential findings accompanying drop in the body temperature of the hibernators are: 1) progressive reduction in amplitude of both microphonic and neural components below about 30° C; with 2) ultimate disappearance of the neural components. The greater the intensity of the acoustic stimulus the lower the temperature at which this disappearance is observed. With our most intense click (about 85 db above human threshold) the neural component in the bat could not be observed below 11° C. 3) A constant latency for the microphonic component over the entire temperature range, and 4) a striking progressive increase in latency of the neural components as the temperature is reduced below about 30° C. The changes in amplitude and latency are essentially reversible as an animal is cooled and warmed through a temperature cycle.

Comparative physiology of cardiovascular pressor reflex mechanism under head-to-tail acceleration (negative G) SHELDON ROSENFELD AND CHARLES F LOMBARD (introduced by CHESTER HYMAN) *Dept of Aviation Medicine, School of Medicine, Univ of Southern California, Los Angeles*

Studies of the effect of negative acceleration upon four species of animals indicate that certain

species are not suitable for consideration relative to man. Studies of 28 experiments including 10 goats, 10 dogs, 5 monkeys and 3 rabbits and compared with data available for man indicate that the monkey and the dog respond in a manner which most closely parallels the reflex cardiovascular response elicited in man during negative *g*. The goat does not simulate this response pattern. The major changes to cephalic circulation during negative acceleration, as measured from the carotid artery and external jugular vein connected to Statham strain gauges at the level of the brain, include the following. At the onset of radial acceleration the arterio-venous pressure difference in man, monkey and goat is slightly increased but in the dog slightly decreased. During radial acceleration of 15-second duration the arterio-venous pressure difference diminished gradually in man (30%), monkey (12%), and dog (65%), but increases in the goat (65%), and is associated with a bradycardia of various degrees. At the termination of radial acceleration within 1 to 4 seconds the arterio-venous pressure difference drops markedly in man (65%), monkey (40%), dog (60%), and drops to the normal prerun level in the goat. It is believed that at the termination of acceleration the animal or subject experiences the most harmful insult to cerebral circulation. Factors which tend to maintain minute cardiac output, as well as factors preventing generalized vasodilatation should be investigated for possibilities of offering greater tolerance to negative acceleration.

Effects on normal subjects of smoking cigarettes with varying concentrations of nicotine GRACE M. ROTH, *Section on Physiology, Mayo Clinic, Rochester, Minn*

Most investigators agree that smoking of tobacco causes elevation of blood pressure, increase in pulse rate, and vasoconstriction of the peripheral blood vessels of the extremities. Recently Haag and Larson studied a new 'low-nicotine' tobacco which when it was smoked produced much less effect on blood pressure and pulse rate than ordinary cigarette tobacco produced. One hundred ninety-two standard smoking tests, including simultaneous blood pressure, readings, pulse rates and skin temperature measurements, were carried out on 29 normal subjects. Six cigarettes made from the new low-nicotine tobacco were smoked at different times, and the main stream of smoke contained respectively 0.23, 0.55, 1.25, 1.83, 2.47 and 3.00 mg of nicotine. Neither the subjects nor the technicians making the test knew which cigarette was used. As a control, cornsilk cigarettes were smoked. The results were analyzed according to the initial basal heat production of each individual. The

effect on the skin temperatures of extremities of smoking two cigarettes containing the two lowest concentrations of nicotine in the main stream of the smoke was similar for the toes and somewhat greater for the fingers than the effect produced when cornsilk cigarettes were smoked. As the concentration of nicotine increased these effects increased. The nicotine content, therefore, should be decreased by at least 50% to prevent the vasoconstriction produced by the smoking of standard cigarettes. Likewise, a definite increase in the blood pressure and pulse rate occurred with increasing concentrations of nicotine in the cigarettes.

Potentiation of the gastric secretory response to other stimuli by caffeine JAMES L. A. ROTH (introduced by JULIUS H. COMBROE), *Dept of Gastroenterology, Graduate School of Medicine, and the Harrison Dept of Surgical Research, Univ of Pennsylvania, School of Medicine, Philadelphia*

Caffeine has been shown to potentiate histamine-induced gastric secretion in cat and man (*Am J Physiol* 142:107, 1944). In cats anesthetized with ether and prepared with a gastric cannula, the effect of caffeine upon other stimuli to gastric secretion was investigated. Urecholeline, 0.01-0.1 mg i.v., had little or no stimulating action, but evoked a marked secretory response when given after caffeine. This occurred whether the dose of caffeine itself was sufficient (35 mg base/kg) or insufficient (20 mg base/kg) to stimulate. Similar observations were made with liver extract (gastric instillation 30 units for 30 minutes) and caffeine. When the secretory rate had declined in response to repeated injections of urecholeline (0.02-0.1 mg intravenously every 15 minutes), a superimposed single injection of caffeine markedly augmented the output of acid secretion. These results have important implications in the dietary management of ulcer patients and in understanding their sustained gastric secretory response to caffeine.

Early divergence of pathways of aerobic and anaerobic glucose metabolism in yeast A. ROTHSTEIN, L. HURWITZ* AND R. MEIER* *Div of Pharmacology, Dept of Radiation Biology, Univ of Rochester School of Medicine and Dentistry, Rochester, N. Y.*

Inhibition of glucose consumption of yeast by uranium is associated with formation of a stable complex between uranyl ion and certain cell-surface loci necessary for initial reactions between the cell and this substrate. Although relatively low concentrations of uranium completely inhibit both aerobic and anaerobic metabolism of glucose, marked differences have been observed in the inhibition curves. With uranium concentrations

below 10^{-6} M (yeast concentration, 5 mg/ml), there is no appreciable effect on anaerobic metabolism, but aerobic metabolism is inhibited up to 30%. With uranium concentrations between 10^{-6} and 10^{-2} M, the anaerobic inhibition curve passes from essentially zero to 100%, whereas the aerobic curve passes from 30% to only 70% crossing the anaerobic curve at about 60% inhibition. Only at 10^{-4} M uranium is aerobic metabolism completely inhibited. A marked difference has also been found by kinetic studies. The relationship between glucose concentration and rate of metabolism obeys the Michaelis-Menton equation both anaerobically and aerobically. In the presence of an inhibiting concentration of uranium, anaerobic metabolism still obeys the Michaelis-Menton equation but aerobic metabolism is quite different, following a complex hyperbolic function. It can be concluded that the aerobic and anaerobic pathways of metabolism diverge at or before the reactions inhibited by uranium. These reactions are known to occur on the cell surface and to involve the initial steps in glucose metabolism.

Movements of the dog's heart in the closed chest

H W RUDEL,* A SOKALCHUK,* G C RING
AND G J NAVIS * *Temple Univ Med School,*
Philadelphia, Pa

In order to better interpret the electrokymographic records obtained over the heart, movements of the dog's heart have been studied. Markers, opaque to x-rays, were placed on the surface of the right and left ventricles. The pericardium and chest walls were then closed so that the conditions for cardiac contraction were approximately normal. Our observations with this preparation differ somewhat from those made by Burchell and Visscher on the isolated heart. The base of the heart moves predominantly toward the apex and the posterior portions move toward the sternum. Early in systole, these sternal movements are much greater on the right than on the left side. This suggests a clockwise rotation of the heart (apical view) at this time. Rotatory ballistic forces in the dog and man are being investigated to further clarify these observations. The first rotatory ballistic force in the dog and man is clockwise.

Stethography of the heart sound intensity envelope

ROBERT F RUSHMER *Dept of Physiology and Biophysics, Univ of Washington School of Medicine, Seattle*

Heart sounds have been recorded as a logarithmic intensity envelope by incorporating a delay of 0.03 sec in the response of a logarithmic amplifier. Since the resulting record corresponds to a continuous line joining the wave peaks on a standard stethogram, a direct-writing penmotor (80 cycles/sec) can respond uniformly to the

amplitude of frequencies ranging from 30 to 2000 cycles/sec. By means of a series of filters, the frequency components of heart sounds and murmurs are analyzed. A major portion of the sounds appear between 30 and 150 cycles/sec, but both sounds and murmurs have components between 150 and 350 cycles/sec. A high pass filter attenuates sounds below 300 cycles/sec, to disclose high-pitched, low-intensity murmurs. Timing of murmurs and identification of adventitious sounds are facilitated by simultaneous recording of the log intensity envelope, an electrocardiogram, a pneumogram and a linear stethogram (frequency range 5-40 cycles/sec on a 4-channel, direct-writing instrument). The linear stethogram has proved useful for timing murmurs, since a high amplitude vibration is associated with the first sound at the apex and with the second sound at the base. Even the loud murmurs in congenital heart disease do not obscure these prominent excursions which appear to have a constant relation to the heart sounds.

Phosphate turnover in the liver in alloxan diabetes

JACOB SACKS AND BARBARA DAMAST *
Brookhaven Natl Lab, Upton, N Y

The effect of alloxan diabetes on the partition of the acid-soluble phosphorus compounds of liver and on their turnover rates has been studied in rats of the Sprague-Dawley strain. The tracer experiments were carried out several weeks after the administration of the alloxan, when the animals showed marked hyperglycemia, polyuria and glycosuria. They were not losing weight. Access to food and water was allowed up to the time of injection of the tracer phosphate, which was given subcutaneously. The inorganic phosphate content of the liver in these animals was about 50% higher than the normal range. The ATP-ADP and glucose-1-phosphate contents were reduced below normal. In the tracer experiments it was found that the P^{32} was removed from the plasma at a much greater initial rate than in normal animals. In the first few hours after the injection of the tracer phosphate, the relative specific activity of the P of the glucose-1-phosphate fraction was higher than that of the labile P of the ATP-ADP. This is the reverse of the situation found previously in the normal animal.

Factors influencing contraction of embryonic heart cultures (motion picture)

MACHTELD E SANO (introduced by DEAN A COLLINGS) *Dept of Tissue Culture, Temple Univ Med School and Hospital, Philadelphia, Penna*

Embryonic heart of the mouse can be used to study the effect of environmental changes such as heat and cold as well as the effect of different chemicals on the contraction of the heart muscle. This method gave consistent results with frag-

ments removed from 150 different embryos of approximately 7-8 days. Cinemicrophotography of the effect of heat and cold and toxins illustrates these findings. The medium is composed of Tyrodes solution, chicken plasma and mouse embryonic extract. Grown for 3 days the fragment shows good regular contractions. After 5 days toxic effects are noted. Contractions are irregular and decreased in amplitude. After washing and refreshing a more normal beat is gradually acquired. Lowering of the temperature to 24°C prolongs contraction for 24 hours. Lowering the atmospheric temperature to zero apparently arrests contraction. However, the cinephotographic record reveals areas of contraction which missed when studied under the microscope. Maximum length for which this fragment can be maintained at 0°C is 5-6 days. On reheating contractions are resumed. Calcium produces decrease in amplitude but increased duration of contraction period. Digitalis in a dilution of 1-100 cat units produces increased duration of contraction. Tissue culture of embryonic mouse heart is a simple, reliable and inexpensive method for testing the influence of physical and chemical factors on heart muscle contraction.

Effect of adrenalectomy on 'salt' hypertension

LEO A. SAPIRSTEIN,* WILBUR BRANDT* AND DOUGLAS R. DRURY, *Dept. of Physiology, Univ. of Southern California School of Medicine, Los Angeles*

Substitution of hypertonic sodium chloride solutions for the drinking water induces an arterial hypertension in the rat (Sapirstein, L. A., W. Brandt, and D. R. Drury. In press). In studying the mechanism of this hypertension we have investigated the role of the adrenal cortex in its maintenance by removing both adrenal glands after the hypertension was well established. Rats made hypertensive with hypertonic sodium chloride were used. After hypertension was established, the experimental animals were bilaterally adrenalectomized, and the controls unilaterally adrenalectomized. Blood pressures were followed with the tail plethysmograph for 3 weeks after the procedure, the animals continuing to receive hypertonic sodium chloride as a substitute for the drinking water. The average systolic pressure in the experimental group was 145 mm Hg before the procedure and 147 mm Hg after the procedure. The control group showed an average systolic pressure of 142 before the procedure and 146 after the operation. No adrenal tissue was found at autopsy. These results indicate that 'salt' hypertension is not dependent on the presence of the adrenal cortex.

Effects of ureteral ligation on renal function in the anesthetized dog

O. W. SARTORIUS (introduced

by W. D. LOTSPEICH) *Dept. of Physiology, Syracuse Univ. Med. College, Syracuse, N. Y.*

The alterations in renal function of the anesthetized dog produced by ureteral clamping have been investigated. When catheters, inserted into each ureter, are separately clamped for periods approximating one hour in duration urine flow from the clamped side is found to increase with removal of the clamp in spite of lowered filtration rate. No significant change occurs in renal plasma flow nor in electrolyte excretion. It would appear that ureteral ligation of such duration partially blocks the active reabsorption of water for periods ranging up to 2 hours after the clamp is removed. Posterior pituitary inhibition is not a factor in the resultant diuresis as the contralateral control kidney is not altered by the procedure.

Pharmacological blockade of pituitary activation in the rabbit and the rat

CHARLES H. SAWYER, J. E. MARKEE AND JOHN W. EVERETT* *Dept. of Anatomy, Duke Univ., Durham, N. C.*

A study was made on effects of blocking agents of adrenergic, cholinergic, ganglionic and central synapses on neurohumoral control of LH release from the adenohypophysis. With the chloroethylamine derivatives SKF-501, Dibenamine and 2-dibenzylaminoethanol, a positive correlation was found in the rabbit between ability to block the cortical stimulus from reaching the hypophysis and capacity to protect against twice-lethal dosages of epinephrine. A negative correlation was observed between central excitatory activity of these agents and their potency in blocking pituitary activation. The rat pituitary-activation mechanism reacted to these drugs in a manner almost identical to the rabbit response. The results are consistent with the hypothesis that these agents prevent pituitary activation by adrenergic blockade. The imidazoline derivatives, Prisco and C-7337, failed to block pituitary activation in either species, although C-7337 develops rapid protection against epinephrine toxicity. The failure cannot be attributed to inability of these agents to reach the effector cells, it would appear more likely that imidazoline derivatives fail because they lack the particular chloroethylamine property which blocks the *natural* adrenergic mediator (not necessarily epinephrine itself). The anti-cholinergic drug, atropine, was successful in blocking pituitary activation in both species, the central anesthetic, Nembutal, was effective in the rat but not in the rabbit, the ganglionic blocking agent, tetraethylammonium, failed in both species. Assuming that Nembutal failed in the rabbit because of temporal considerations, these collective data suggest that the site of atropine-block is located between the hypothalamus and the hypophysis.

Cerebral metabolism in hyperthyroidism and myxedema PRITZ SCHINBERG (introduced by EUGEN A. STFAH, JR.) *Dept of Medicine, Duke Univ School of Medicine, Durham, N C*

Cerebral blood flow and metabolism were measured by means of the nitrous oxide technique in 9 subjects with hyperthyroidism and in 8 subjects with myxedema. Three patients with myxedema were restudied after clinical improvement on thyroid therapy. The subjects with hyperthyroidism showed no significant variation from normal in any of the measured cerebral metabolic functions. This is of considerable interest in view of the 35% increase in cardiac output and 60% increase in splanchnic oxygen consumption that is known to occur in a similar series of hyperthyroid patients. The patients with myxedema showed reductions in cerebral blood flow (38%) and oxygen consumption (27%) commensurate with the fall in cardiac output and total oxygen consumption that is known to occur in these patients. Cerebral glucose consumption decreased in proportion to the decrease in cerebral oxygen consumption. Cerebral vascular resistance was increased almost 100%, and definitely decreased following treatment. The cerebral metabolic functions returned toward normal, in conjunction with clinical improvement, in the 3 patients restudied after thyroid therapy. These data indicate that in hyperthyroidism the brain does not share in the general increase which occurs in body metabolism, and that the clinical signs of mental dysfunction so commonly observed in myxedema may be accounted for by the decreased cerebral metabolism in this disease.

Site of action of Dramamine and Benadryl in correction of forced circling movements and of convulsant brain wave patterns induced by di-isopropyl fluorophosphate (DFP) M. SCHIFF,* W. G. ESMOND* AND H. E. HIMWICH *Medical Div., Army Chemical Center, Md*

The intracarotid injection of di-isopropyl fluorophosphate (DFP) produced an adverse syndrome turning of the head and forced circling, away from the injected side. Section of the 8th revealed that in the rabbit and cat the peripheral vestibular receptors exerted a conditioning influence while in the monkey the response remained unaltered by the 8th nerve section (C. F. Essig, J. L. Hampson and H. E. Himwich). These results afford evidence for a central cholinergic mechanism for the forced circling, a conclusion supported by the fall of cholinesterase activity observed in cerebral structures and particularly in the homolateral caudate nucleus with the smaller turning doses. In the present experiments on cats DFP in subconvulsant doses was 1) injected through the tympanic membrane 2) placed against the

round window 3) injected through the round window and uniformly failed to evoke forced circling, proving the dispensability of the peripheral vestibular receptors for this syndrome. Dramamine, 5 mg/kg, injected i.v., corrected the forced circling movements in 8 rabbits. Similarly Benadryl, 5 mg/kg, restored normal behavior in 1 other rabbit previously exhibiting the syndrome. Dramamine, 10 mg/kg, prevented forced movements in 4 rabbits subsequently injected with DFP.

DFP, in convulsant doses, was used to induce grand mal-like electrocorticograms in curarized artificially respired rabbits. Dramamine or Benadryl administered intravenously after DFP restored the normal electrocorticogram, and injected before DFP, prevented the seizure pattern. It is suggested that the atropine-like action of these 2 antihistamines, exerted centrally, is the basis for their therapeutic effects.

Kidney physiology of the desert rat *Dipodomys merriami* BODIL SCHMIDT-NIELSEN *Kettering Lab., Univ. of Cincinnati, Cincinnati, Ohio*

The kidneys of the desert rats *Heteromyidae* have been found to be able to perform unusual osmotic work. Electrolyte concentrations up to 1.2 M and urea concentrations up to 3.8 M have previously been reported. A closer study of the kidney physiology and histology was undertaken. Studies of the creatinine clearance indicate that the glomerulus filtration is proportional to the urine flow, and that the reabsorption of water in the tubuli in the desert rats may be 2-3 times as high as the reabsorption in the tubuli in the white rats.

Evidence for physiological activity in nerve membrane in response to subthreshold stimulation OTTO H. SCHMITT AND PETER A. STEWART* *Depts. of Zoology and Physics, Univ. of Minnesota, Minneapolis*

The electrical admittance of nerve membrane has been measured by the complex attenuation method. For the squid giant axon, the results agree with those of Cole for the frequency regions where both methods are reliable. As the attenuation method is not limited to single fiber analysis and does not require large fibers, its use is being extended to other than squid nerves, and to other cylindrical cells. In the low frequency region, 50-500 cps, which is not readily accessible by conventional methods, anomalous characteristics intimately associated with the physiological state of the nerve have been measured and to some extent interpreted in terms of physico-chemical mechanisms. It is established rather convincingly, for example, that gross structural characteristics of the fiber determine speed of propagation while undetermined physico-chemical membrane factors

account for the anomalous impedance. Even at levels of stimulation only a small percentage of threshold is there evidence for a physiological energy-contributing process, which is strongly time dependent and highly responsive to usual nerve reagents. Preliminary measurements show frog nerve to have average membrane properties similar to those of squid fibers, but these properties are almost completely obscured if the nerve is not freed of its external membranous sheath. A mechanized nomographic complex-plane computer which permits immediate evaluation of admittance results from raw experimental data has been devised and will be described if time permits.

Relation of stress to certain biophysical alterations of the blood in the normotensive and hypertensive subject ROBERT A. SCHNEIDER (introduced by HAROLD G. WOLFF) *Cornell Univ. Med. College, New York City*

This is a preliminary study of the effect of stress on blood-clotting time, blood viscosity, the erythrocyte sedimentation rate and the hematocrit. Subjects included healthy volunteers, hypertensive and nonhypertensive patients. The stress situations included physical exercise, a modified cold-pressor test, a half-hour period at rest where the subject was asked not to move or talk, and finally a stressful interview. Blood was drawn with a silicone treated syringe and needle prior to, immediately after, and finally one hour after stress. Clotting times were measured in siliconized Wassermann tubes (method of Barker and Margulies). The blood viscosity was measured on heparinized specimens using the method of Tang and Wang. The sedimentation rates and hematocrit percentages were both measured in Wintrobe tubes. The sedimentation rates were corrected values. Exercise in healthy adults always resulted in a marked shortening of clotting time, an increase in the blood viscosity, an increase in hematocrit and a decrease in sedimentation rate. Nearly identical findings occurred both in the cold-pressor test, only in the presence of a pressor response, and with the stress interview but again only in those subjects experiencing a pressor reaction. No significant changes occurred in these experiments in the absence of a pressor response. The immobility experiment failed to elicit a pressor reaction and produced changes in the blood opposite to those found after exercise. The significance of these findings as they relate to Cannon's work and to the problem of the hypertensive state is discussed.

Threshold electrotonic potentials of nerve and muscle at different temperatures GORDON M. SCHOEFFLE *Dept. of Physiology, Washington Univ. School of Medicine, St. Louis Mo*
In a frog sciatic nerve, stripped of perineural

sheath, brief conditioning and testing shocks of 0.08 sigma duration elicit electrotonic potentials at the stimulating cathode which summate to a fixed intensity at threshold, regardless of the interval between shocks. The decline of this threshold potential subsequent to the test shock follows an identical time course in each instance. These data are consistent with those previously reported concerning stimulation of stripped nerve or fiber bundles by threshold rectangular currents of various durations. Rheobase is elevated by cooling, but chronaxie and the time parameters of the electrotonic potential are not appreciably altered by a 15° drop in temperature. However, if the sheath is not removed the time parameters of both excitation and electrotonic potential are appreciably increased by cooling, the reciprocal chronaxie with a Q_{10} of 1.15. These data provide strong additional evidence supporting the view that local attainment of a critical outwardly directed potential difference across the distributed membrane capacity is sufficient for excitation of nerve in the absence of accommodation. Stimulation of isolated bullfrog muscle fiber bundles by means of rectangular currents gives rise to electrotonic potentials at the cathode which decline in magnitude as duration of threshold rectangular current stimulus is decreased. However, the time parameters of electrotonic potential and excitability are apparently of the same order of magnitude.

Photometric ninhydrin method for the measurement of proteolysis THEODORE B. SCHWARTZ* AND FRANK L. ENGEL *Dept. of Medicine, Duke Univ., Durham, N. C.*

It has been shown by Moore and Stein (*J. Biol. Chem.* 176:367, 1948) that the color produced by the interaction of an improved ninhydrin reagent with the free amino groups of amino acids and peptides conforms with Beer's Law over a broad range. These findings have been applied to the measurement of the rate of enzymic hydrolysis of a synthetic peptide substrate, L-leucylglycylglycine (LGG). Enzymic cleavage of LGG into L-leucine and GG results in a progressive increase in free amino groups and, consequently, a continuing enhancement of ninhydrin color yields in serial samples withdrawn from an hydrolysis mixture. Theoretical considerations suggested that a direct proportionality exists between percentage hydrolysis of the substrate and the optical density of the ninhydrin color produced in any given sample. Experimental confirmation of this hypothesis has been obtained by measuring the color yield of mixtures containing LGG, GG and L-leucine synthetically prepared to represent varying degrees of hydrolysis. This method is relatively simple and especially time saving when large

numbers of analyses are required. It permits accurate evaluation of enzyme kinetics and gives results that compare favorably with those obtained with the Van Slyke manometric technique. It theoretically may be employed to measure the enzymic hydrolysis of any synthetic peptide substrate.

Comparison of cardiac output determined by the Fick procedure and a direct rotameter method
ROBERT D. SEELY,* WILLIAM E. NERLICH* AND DONALD E. GREGG *Med. Dept. Field Research Lab., Fort Knox, Ky.*

As an accurate standard of reference with which the Fick procedure might be compared, a method was devised for use in open-chest dogs, whereby total cardiac output could be directly and continuously recorded by measuring flow through the pulmonary artery. Such a method avoids the error inherent in other direct procedures (flow meters in aorta and venae cavae) which fail to measure coronary flow. Cardiac output, recorded optically over a 6-minute period by a rotameter connected to the pulmonary artery, was compared with simultaneous measurements made with the Fick method. A modified Benedict-Roth spirometer was used to measure oxygen consumption. Arterial and venous (pulmonary artery) samples were taken continuously over the 6-minute test period and were analyzed in duplicate for oxygen content by the method of Van Slyke and Neill. Duplicate samples were required to check within 0.08 volumes %. In a few experiments, Fick flow values in closed-chest dogs were compared with flows simultaneously measured by a rotameter in the venae cavae. The average variation between the 2 series of measurements was $\pm 4\%$. Twelve of the 13 comparisons made agreed within less than 8%. This small deviation is within the range of summated errors which might exist on the basis of known technical inaccuracies.

Behavior of renal clearance mechanisms under pentobarbital sodium anesthesia
EWALD E. SELKURT AND KIRKWOOD F. GLAUSER* *Dept. of Physiology, Western Reserve Univ. Med. School, Cleveland, Ohio*

Study of renal clearances in dogs under pentobarbital anesthesia, where use of untrained dogs was desired, or in connection with surgical intervention, has made desirable reinvestigation of the possible influence of this anesthetic agent on renal function. We were particularly interested in its possible effect on sodium clearance. After control periods in trained female dogs, full anesthetic doses of pentobarbital were given and clearances of creatinine, PAH, and sodium were followed for as long as 52 hours. It was found that no significant change in CC_r , $CPAH$ and FF oc-

curred during time intervals averaging 73 minutes. During the next 117 minutes, CC_r increased, and $CPAH$ decreased both by small but probably significant degrees so that FF increased significantly. This trend continued to a more marked degree during the final 90 minutes. Sodium clearance was increased about 5-fold during the total time of observation, but emphasis must be placed on the fact that control clearances only averaged ca. 0.25 cc/min. With regard to impairment of tubular efficiency, this indicated only about 2% decrease in reabsorption of the filtered load. A marked effect was however noted on urine flow which decreased to an average of about 30% of the control value during the periods immediately following administration of the anesthetic agent.

Compensatory changes in the rat following depletion of extracellular electrolytes
ROBERT E. SEMPLE (introduced by WALTER S. ROOT)
Dept. of Physiology, College of Physicians and Surgeons, Columbia Univ., New York City

Daily water intake and urine output were measured in a group of young adult rats on a diet made complete by addition of sodium chloride. After one week of daily observation, the animals were given an intraperitoneal injection of 9 cc/100 gm body weight of isotonic glucose solution. One hour later 90% of the injected volume was recovered, and its chloride content determined. After this time sodium chloride was omitted from the diet. For the next 24 to 48 hours the animals exhibited a marked increase in urine output with a concurrent decrease in water intake. After 48 hours a normal relationship between fluid intake and output was reestablished. Fluid loss by way of the kidneys during the period of negative water balance was comparable to the volume of fluid that would be given by up the extracellular fluid compartment if the chloride concentration therein were restored to normal. This predicted loss in extracellular fluid was calculated from the amount of chloride removed in the intraperitoneal glucose solution. Serum chloride concentrations returned to normal within three days. The fluid loss was accompanied by a proportionate loss in body weight. These results indicate that electrolyte depletion in a rat by intraperitoneal glucose is followed by fluid loss sufficient to restore the plasma chloride concentration to normal.

Influence of histamine and anti-histaminic compounds on water imbibition by striated and smooth muscles and gastric mucosa
V. SENCINDIVER,* E. M. LARSON* AND M. H. F. FRIEDMAN *Dept. of Physiology, Jefferson Med. College, Philadelphia, Penna.*

The influence of histamine and anti-histaminic compounds (neohetramine, thephorin) on imbibition

tion of water by straited muscle, smooth muscle from the stomach and gastric mucosa was studied Using fresh tissue derived from the rabbit and the frog, the water imbibed over a period of 24 hours under controlled conditions of pH, temperature, and tonicity was determined The water uptake by rabbit smooth muscle and gastric mucosa was equal to that of similar weights of corresponding frog tissues The water uptake by rabbit striated muscle, however, was much less than by frog striated muscle The water imbibition by rabbit isolated smooth muscle was depressed and often reversed by the addition of histamine On the other hand, antihistaminic compounds either did not inhibit water uptake or at times accelerated it The anti-edemic action of histamine was not related to its motor effects on smooth muscle Other smooth muscle stimulants did not influence water imbibition Rabbit isolated gastric mucosa behaved similar to smooth muscle Pretreatment of the animal with anti-histaminics was not found to affect the rates of water imbibition by the isolated tissues These results do not support the views of certain French investigators on the anti-edemic properties of anti-histaminic compounds

Results suggesting endocrine participation in experimental renal hypertension ROGER W SEVY,* DOROTHY HAASCH CHESSE* AND GEORGE E WAKEBLIN *Dept of Physiology, Univ of Illinois College of Medicine, Chicago*

Crude beef anterior pituitary extract was administered 1 m (0.5–1.0 gm of wet gland equivalent/per/kg of body weight/per day) to 4 renal hypertensive dogs for 2–5 months and to 4 normotensive dogs for 1–6 months preceding and up to 1 month following bilateral renal artery constriction Of the 4 renal hypertensive dogs, 2 showed an excellent and one a moderate antihypertensive response after 2 months of treatment, the 4th showed no response The antihypertensive response in one dog was temporarily reversed by desoxycorticosterone acetate overdosage Of the 4 normotensive dogs, one, which received the longest course of treatment, showed no rise in blood pressure following constriction of the renal arteries despite marked reductions in TmPAH and the renal clearance of PAH and creatinine Two showed no rise in blood pressure following constriction of one renal artery but died, with the clinical and pathological picture of malignant hypertension, following constriction of the contralateral renal artery The 4th developed typical chronic hypertension Further possibility of endocrine involvement in experimental renal hypertension is suggested by the finding of a decrease in sensitivity to insulin and a somewhat lower fasting blood glucose level in 10 renal hypertensive as compared to 9 normotensive dogs

Potassium shifts in nerve A M SHANES *Dept of Physiology and Biophysics, Georgetown Univ School of Medicine, Washington, D C*

Electrical studies of *Rana pipiens* sciatics and *Libinia emarginata* leg nerves indicate that resting potential fluctuations are due largely to potassium movement A sensitive method to detect such potassium shifts is presently being employed It consists of collecting 1 ml samples of medium successively placed in contact with paired sets of 3 or 4 nerves Potassium analyses of the individual samples are made with the Beckman flame spectrophotometer Typically, repeated collections are made first in oxygen, then in nitrogen, and finally in oxygen again *Libinia* nerves lose 20 μ M potassium/gm wet weight/hr in oxygenated sea water whether glucose is present or not, anoxia doubles or trebles this loss, and 50–100 mM glucose reduces this increment, return to oxygen either completely stops potassium escape or causes an absorption of potassium Intact *Rana* sciatics, following equilibration for 1 hour in oxygenated $\frac{1}{2} \times$ Ca Ringer's solution, lose 0.4 μ M potassium/gm/hr, mere removal of the perineurium causes 3 of the nerve potassium to escape during equilibration, but negligible loss occurs thereafter Both types of preparation release potassium during anoxia, usually at a rate increasing with time which averages 1.4 μ M/gm/hr over 3 to 4 hours Return to oxygen causes an absorption of potassium in the absence of the perineurium (10 μ M/gm/hr), or cessation of leakage with the intact sheath Cocaine (0.1%) halves the anoxic escape of potassium without altering recovery, In normal Ringer's similar effects are observed but the magnitude of the differences appears to be less

Electrocardiographic age trends E SIMONSON *Lab of Physiological Hygiene, Univ of Minnesota, Minneapolis*

Means, standard deviations, medians and percentile distribution of 34 electrocardiographic items in the 3 standard leads and CF₄ were compared in a group (I) of 157 normal men from 17 to 25 years and a group (II) of 233 normal men from 45 to 55 years Most items showed statistically highly significant differences ($p < 0.01$) between the means of the two groups At the older age there were significant increases in the P-R interval and in KQT (= square root of R-R interval divided by Q-T interval), decreases in the QRS and T amplitudes, especially in the standard leads, and a shift to the left in the QRS and T axes The arrhythmia index (difference between the smallest and largest R-R interval) declined from a mean of 0.016 in group I to 0.044 sec in group II Both groups included men in all weight categories in a similar proportion Comparison

of partial groups of 49 younger men and 66 older men within $\pm 5\%$ of their standard weight revealed differences similar to those obtained between the total groups. The observed age trends are, therefore, not due to weight differences. The frequency distribution of most items was asymmetrical, but similar in both groups. The age differences in many items are large enough to be of importance for routine clinical interpretation. Age corrected standards were calculated from the standard deviations or percentile distribution. Statistically highly significant age trends were also observed in VR, VL, and VF.

Inactivation of thrombin and fibrinogen by tyrosinase IRVIN W. SIZER AND PHILIP F. WAGLEY *
Dept. of Biology, Massachusetts Inst. of Technology, Cambridge, and Johns Hopkins Hospital, Baltimore, Md

When commercial thrombin (Upjohn, Parke-Davis, or Armour) was incubated in phosphate buffer, pH 6.0, at 37° with commercial tyrosinase (Treemond or Synzyme) there was a marked inactivation of the thrombin. This was measured by determining clotting time after the addition of an aliquot of thrombin to a standard amount of fibrinogen (Armour) at 25°. In a typical experiment, incubation of thrombin with tyrosinase resulted, after 6 hours, in a change in clotting time from 0.4 min to 2.5 min. Although the rate of clotting was changed, the amount and nature of the final clot formed was independent of any previous treatment of thrombin by tyrosinase. Dialysis experiments indicated that the inactivation was not mediated by low molecular weight impurities in the thrombin. Similar studies were made on the inactivation of crude (Armour) and purified fibrinogen by tyrosinase. The inactivation occurred slowly at first and then at an increasingly rapid rate so that in 3 hours the clotting time, when tested by the addition of thrombin, had changed from 0.4 min to 20 min. The amount of clottable protein correspondingly decreased as a result of the inactivation of fibrinogen by tyrosinase. The clot obtained from fibrinogen oxidized by tyrosinase was very different from that obtained from normal fibrinogen. Studies with the electron microscope indicated that the fibrin from normal fibrinogen was characterized by fine fibrils, while that from fibrinogen oxidized by tyrosinase appeared completely amorphous. Preliminary studies in the ultraviolet indicate that tyrosinase will produce a change in the absorption spectrum of both thrombin and fibrinogen and perhaps of fibrin as well.

Exercise following whole-body irradiation of mice
FALCONER SMITH AND WILLIE W. SMITH *Lab of Physical Biology, Experimental Biology and*

Medicine Inst., Natl. Insts. of Health, Bethesda, Md

In studies of metabolic factors which may be involved in the irradiation syndrome various stresses are imposed upon mice following whole-body x-irradiation. Information concerning exercise may be of practical as well as physiological importance. Mice were exercised in a cage with individual tracks 48 cm in diameter making 3 revolutions/minute. Controls tolerated this for 12 consecutive hours, or 8 hours/day on 3 consecutive days, with only transitory weight loss. The tests were considered severe enough for our purpose because many mice, after a week of thyroid administration, failed to exercise for more than a few hours, some of them dying during the test. Mice given x-ray in the low lethal dose rate (325 r) tolerated 12 hours of exercise immediately after or up to 16 days after irradiation. Mice given 400 r tolerated exercise 8 hours/day for 3 consecutive days beginning immediately after or up to 13 days after irradiation. Survival time and mortality were affected, if at all, in no more than 20% of these mice. After 600 r both irradiated controls and those exercised 8 hours/day on days 0, 1, and 2 post-irradiation died, 20% of the latter group during exercise, the remaining at about the same times as the controls. Radiation did not markedly decrease ability to tolerate exercise, nor did exercise markedly increase mortality or decrease survival time of irradiated mice. These studies are being continued.

Further observations on the action of curare

JAY A. SMITH, MELVIN POST AND SHERWIN ZALMAN (introduced by L. B. NICE) *Dept. of Physiology and Pharmacology, Chicago Med. School, Chicago, Ill*

Smith *et al* (*J. Pharmacol. & Exper. Therap.* 93: 294, 1948) show that neutralized thiamine solutions are without effect on the isolated heart and (*Science* 108, 412, 1948) that the action of thiamine is that of a curariform drug. McIntyre (*Curare*, University of Chicago Press) shows that the action of curare drugs is to raise the threshold to acetylcholine. In the present experiments on the isolated turtle heart, curare preparations abolish or reduce the inhibiting effects of acetylcholine. After atropinization of the isolated heart, curare drugs abolish the stimulating effects of acetylcholine. These results indicate that, in the absence of acetylcholine, the typical effects of curare drugs are absent. In anesthetized dogs, curare preparations (d-tubocurarine, Squibb, and thiamine) cause a fall in blood pressure, followed, in most cases, by a rise to a level higher than the control level. In addition, after the injection of curare preparations, prostigmine frequently causes a marked rise in

blood pressure and increase in the heart rate (these effects may be prevented by dibenamine and tetraethylammonium bromide). Thus, in addition to the possibility of a stimulation of the adrenergic endings by acetylcholine, these results may be interpreted to mean that the effects of curare persist longer in the parasympathetic ganglia than in the sympathetic ganglia.

Non-olfactory functions of the pyriform-amygdaloid-hippocampal complex WILBUR K. SMITH
Dept of Anatomy, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y

On the basis of the results of excitation and ablation, the pyriform-amygdaloid-hippocampal complex can now be considered to have transcended its role as a part of the olfactory apparatus and to participate in various ways in the general behavior and reaction patterns of the mammalian organism. Excitation of the posterior pyriform region in both cat and monkey produces a variety of responses mostly in the autonomic realm (*Federation Proc* 3 43, 1944, *Anat Rec* 100 713, 1948). Extirpation of this region in the monkey appears to produce no gross motor or sensory changes, but there is a remarkable alteration in behavior and in the reaction patterns of the animal. Activity is decreased so that the animal not only moves less, but more slowly than before operation. Fear and the defensive and offensive reactions associated with it have disappeared, and the animal permits itself to be handled with little or no resistance. It will now approach and take food from the observer either with its hand or mouth. Another aspect of altered activity may be designated as oral compulsive behavior. Objects placed within its reach are picked up in an apparent indiscriminate manner, brought to the nose, then placed in the mouth and if edible are ingested, if not are discarded, sometimes after chewing. Investigations designed to determine the role of the components of the pyriform-amygdaloid-hippocampal complex in the altered behavior have shown that the loss of the fear and defensive reactions can be produced without the compulsive oral behavior.

Effect of insulin-induced hypoglycemia on contraction of human gall bladder W J SNAPE, RUSSELL WIGH* AND M H F FRIEDMAN *Dept of Physiology, Jefferson Med College, Philadelphia, Penna*

The influence of vagal stimulation on the evacuation of the human gall bladder was studied in subjects without evidence of biliary tract disease. Hypoglycemia induced by insulin was used to stimulate the vagus. Evidence of gall bladder contraction was obtained by 1) radiographic examination of the visualized gall bladder and 2) determination of the bilirubin concentration of

the duodenal contents obtained by constant aspiration. In subjects previously found to show a normal gastric secretory response to histamine the production of insulin hypoglycemia resulted in evacuation of the gall bladder providing the acid gastric contents were permitted to enter the duodenum. In subjects found to be histamine-refractory the gall bladder contracted only slightly, or not at all, after the administration of insulin. It is concluded that in the human the contraction of the gall bladder may be chiefly under hormonal (cholecystokinin) mechanism.

Influence of cerebellar cortex on incoming cerebellar volleys RAY S SNIDER AND P M COOKE*
Dept of Anatomy, Northwestern Univ Med School, and Dept of Psychiatry, Univ of Illinois Med School, Chicago, Ill

The altered electrical activity of efferent cerebellar volleys in the brachium conjunctivum was visualized on a cathode ray screen (Grass Model III amplifier) following application of electrical stimuli of various frequencies and wave forms to 1) brachium restiformis, 2) cerebellar cortex and 3) central cerebellar nuclei. Electrical activation of brachium restiformis with single pulses results in modified activity at a cortical level and also in the appearance of repetitive waves approximately 30 msec apart and 30 msec duration at a conjunctival level. Similar waves have been observed following stimulation of nucleus dentatus. Effects of such physiological stimuli as 'auditory clicks' on the above systems are being studied. The most pronounced changes observed at a conjunctival level following application of single pulses to cerebellar cortex is an approximate doubling in amplitude and halving in frequency. Attempts are being made to relate these observations to certain known intrinsic cerebellar activities. Most of the above observations were made on cats prepared according to an 'isolated encephalon' technique and upon animals following ether, novocaine and beta-erythroidine narcosis. Similar observations could not be made following barbiturate anesthesia.

Changes in carbon dioxide-combining power of fetal blood FRANKLIN F SNYDER *Depts of Obstetrics and Anatomy, Harvard Med School, Boston, Mass*

A striking decrease in the carbon dioxide combining power of the fetal blood occurs as pregnancy is prolonged beyond term. In postmature rabbit fetuses, delivered at 35 days, which is the limit for survival of the fetus within the uterus, the carbon dioxide combining power averaged 31 volumes % in contrast to 40 observed in fetuses delivered at term, i.e. 31 days. At the stage of prematurity, 29 and 20 days, the fetal blood averaged 41. In previable fetuses at 27 days, the

blood averaged 39. Observations were made upon a series of 85 fetuses operatively delivered at various stages of pregnancy ranging from pre-viability to postmaturity. Determinations of the carbon dioxide combining power with the Van Slyke apparatus were carried out on 0.5 cc samples of plasma obtained from neck veins.

Effect of acute experimental polycythemia on renal blood flow. MERRILL P. SPENCER, KIRKWOOD F. GLAUSER AND PHILIP W. HALL (introduced by J. M. HAYMAN, JR.) *Dept. of Physiology, Western Reserve Univ. Med. School, Cleveland, Ohio*

When dogs were cross-transfused with matched blood in acute experiments, it was found that after a 2-hour interval had elapsed hemoconcentration had occurred without significant increase in blood volume and with readjustment of mean arterial blood pressure to approximately control values. Although the exact mechanisms of the compensatory changes are obscure at present, the increase in blood viscosity predicated on the increase in the hematocrit value offered an interesting problem in renal hemodynamics. It was found that effective renal blood flow, as measured by PAH clearance and the hematocrit percentage, had changed little. Further, glomerular filtration rate as measured by the creatinine clearance was on the average not significantly different from the control values. However, marked decrease in the effective plasma flow as measured by the PAH clearance had occurred (-22 to -51%). This gave significantly elevated filtration fraction values. When proper allowance was made for the expected increase in viscosity resulting from the increased hematocrit value, the well-maintained total renal blood flow suggested dilatation in the renal vascular circuit. Since such dilatation was accompanied by an elevation of the filtration fraction, the conclusion was reached that it occurred predominantly in the afferent arteriole.

Ratio of myosin to actin in synthetic actomyosin. S. S. SPICER AND J. GERGELY (introduced by LOUISE H. MARSHALL) *Experimental Biology and Medicine Inst., Natl. Insts. of Health, Bethesda, Md.*

Addition of adenosine triphosphate (ATP) to a colloidal suspension of myosin and actin at 0.13 M KCl and pH 7.5 causes superprecipitation. It has been assumed that these 2 components combine in almost any proportion to form actomyosin (A. SZENT-GYÖRGYI *Muscular Contraction*, N. Y., 1947). The ratio in which the 2 proteins combine during superprecipitation with ATP has been investigated. Increasing amounts of actin were added to a constant amount of myosin and vice versa. The supernate after removal of the precipitate by centrifugation was tested for presence

of both myosin and actin, and the total protein in precipitate and supernate was determined. One ratio was always found in which the supernate contained no myosin or actin. This indicates a stoichiometric ratio of myosin to actin. Myosin (or actin) added in increasing amounts beyond the stoichiometric point appeared part in the supernate and part in the precipitate up to a certain limit. All of the protein added beyond this limit was found in the supernate. This indicates a loose secondary association of the 2 components. Electrophoretic analysis showed less than 2% impurity in the myosin, but 30% or greater impurity in the actin. Therefore, protein left in the supernate at the stoichiometric point probably derived from the actin. Subtracting this protein from the actin added at the stoichiometric ratio gives a myosin:actin ratio of roughly 4:1 by weight.

Attempts to record human electro labyrinthogram.

E. A. SPIEGEL, H. T. WYDIS* AND CH. UMLAUF*
Dept. of Exper. Neurology, Temple Univ. Med. School, Philadelphia, Penna.

In order to pick up the electrical discharges of the statokinetic labyrinth and/or of the 8th nerve, various electrode positions were tried such as intermeatal, meatal-mastoid, meatal-retromastoid, meatal-suboccipital combinations. The meatal-retromastoid combination seems most promising, with the meatal electrode close to that part of the posterior wall of the external auditory meatus which is connected by the antrum bridge to the external semicircular canal. In order to study the question whether one picks up labyrinthine discharges, the electrogram was recorded before and after rotation in cases in which the 8th nerve had been cut or destroyed by tumors unilaterally and in which the sensory receptors of the labyrinth probably were also degenerated due to interruption of the circulation of the internal auditory artery on the operated side. In order to minimize artifacts due to the postrotatory nystagmus the patient looked after rotation in the direction of the slow component of the postrotatory nystagmus, if a nystagmus of central origin was intensified in this direction, the patient looked straight ahead. The eyes were kept open in order to suppress α waves of cortical origin. Under these experimental conditions, discharges could be picked up, which showed a definite postrotatory increase of the amplitude compared to those recorded in the resting stage, at least in single instances, this increase was limited to the side of the intact labyrinth or intact 8th nerve.

Effects of lesions of human thalamus in region of dorsomedial nuclei. E. A. SPIEGEL, H. T. WYDIS,* H. SHAI, K. B. CONGER* AND H. K. FISCHER. *Depts. of Exper. Neurology, Neuro-*

surgery, Urology, and Fels Foundation, Temple Univ Med School, Philadelphia, Penna

Lesions in the area of the dorsomedial nuclei were produced by means of the stereotaxic method in psychotics, epileptics, and in cases of unbearable pain. The location of the lesions was checked postoperatively by roentgenologic studies determining the relationship of pantopaque droplets injected at the site of the lesion to the pineal gland. Such lesions frequently produced transitory disturbances of orientation, particularly for time, and transitory defects of memory affecting recent as well as remote events. There were no significant changes of pain threshold and no disturbances of the so-called psychoreflexes. Changes in the realm of the vegetative system, however, could be observed. Pharmacodynamic tests chiefly revealed a shift of balance between the sympathetic and the parasympathetic system in favor of the former. Studies of the glucose tolerance showed a decrease of the postprandial hyperglycemia in cases in which the peak of the hyperglycemia after ingestion of glucose exceeded 180 mg. Alterations of the blood lipides and disturbances of liver function could not be found. Incontinence of the urinary bladder or precipitous micturition developed rather frequently, and cystometric measurements revealed, at least in single instances, a hyperirritability of the urinary bladder. All these disturbances of vegetative innervation were of transitory nature. It is suspected that they are due to the loss of impulses that are transmitted by periventricular fibres from the dorsomedial nuclei to the hypothalamus.

Isolation and characterization of two adaptive enzymes formed by yeast in response to maltose S SPIEGELMAN, M SUSSMAN* AND B TAYLOR * *Dept of Bacteriology, Univ of Illinois, Urbana*

Recent work by Monod (*Compt rend Acad d sc* 227 240) and Doudoroff, *et al* (*J Biol Chem*, 179 921) has demonstrated that the enzyme formed by *E coli* in response to growth in the presence of maltose is an 'amylomaltase'. A similar examination in the case of a strain of *S cerevisiae* revealed that adaptation to maltose leads to the production of two enzymes, neither one of which is an amylomaltase. The material used consisted of fast, efficiently dried cells, harvested at 18-24 hours from a well aerated culture (6 l) incubated at 30°C. Dried preparations prepared from cells either grown in a medium containing maltose, or adapted to maltose in resting suspension subsequent to harvesting, possessed the capacity to split maltose and α -methylglucoside. Similar glucose grown preparations were inactive against both substrates. The enzyme activity is extracted with $M/15 (NH_4)_2HPO_4$ (AP)

and precipitated from the supernate with ammonium sulphate (AS) at 75% saturation. Reprecipitation with AS at 45% saturation yields a precipitate containing 65% of the activity of the original AP extract. Dialysis of the second AS precipitate against large volumes of distilled water resolves the activity into 2 components. One, a fraction which precipitates during dialysis (enzyme I) and the other remains in the supernate (enzyme II). Enzyme I was shown to be a maltase capable of splitting maltose into 2 glucose molecules, as demonstrated by quantitative recovery experiments, chemical analysis based on reducing power and paper strip chromatography. The involvement of phosphate was eliminated since the enzyme functioned equally well in the absence of phosphate. Enzyme I is completely unable to split α -methylglucoside, but can hydrolyze α -phenylglucoside. Enzyme II, on the other hand, cannot split maltose or α -phenylglucoside appreciably but is very active against α -methylglucoside. Both enzymes are activated by cysteine. It should be noted that the intact cell from which these enzymes were obtained possesses no detectable capacity to split α -methylglucoside, whether it be adapted to maltose or not. No intact cell of this strain can be adapted to utilize α -methylglucoside.

Variation of respiratory quotient during normal and deep exhalation RALPH W STACY AND GEORGE H KYDD, III * *Lab of Aviation Physiology, Ohio State Univ, Columbus*

Preliminary studies on expired air made by means of the mass spectrometer and already reported showed that the first air leaving the lungs has a higher R Q than has the end of the expiration. Experiments have been designed and carried out which prove that these changes in the R Q are not the result of instrumental or technical errors. In further experiments during which expired air was collected and flow patterns recorded, the pO_2 and pCO_2 of expired air have been measured by means of the mass spectrometer. The R Q's of different fractions of the expired air were then compared with the R Q of the collected expired air. The results of these experiments indicate that in normal breathing the R Q at the beginning of exhalation is approximately 1.0 and is progressively reduced until at the end of the exhalation it has a value somewhat lower than the metabolic R Q as determined by Haldane analysis. When the tidal volume was increased to from three to five times its normal value the R Q at the beginning of expiration was about 3.0 and fell to about 1.0 by the end of the expiration. These high R Q values may be explained on the basis of the partial pressure gradient existing between the blood in the pulmonary arteries and alveolar air.

Calculations show that the $p\text{CO}_2$ gradient at the beginning of expiration is several times that at the end. On the other hand the $p\text{O}_2$ gradient changes but little during expiration.

Influence of pancreatectomy on lipid metabolism and atherogenesis in the chick I. STAMMER,* C. BOJENF,* L. N. KATZ, R. HARRIS* AND R. PICK* *Cardiovascular Dept., Medical Research Inst., Michael Reese Hospital, Chicago, Ill.*

Effect of pancreatectomy on chick lipid and carbohydrate metabolism and atherogenesis was investigated in a series of acute and chronic studies. In acute experiments, addition of cholesterol plus cottonseed oil to a plain mash diet led to a more marked lipemia in depancreatized chicks than in unoperated controls. Both groups had similar blood glucose levels and glucose tolerance curves. A 5-day course of ACTH had no effect on blood glucose, lipid or eosinophil levels, apparently mammalian ACTH was without demonstrable activity in these chicks. Pancreatized chicks chronically fed a mash supplemented with 2% cholesterol plus 5% cottonseed oil maintained plasma lipid levels consistently and significantly greater than those of unoperated controls on the same diet. This altered pattern of response of depancreatized birds to lipid feeding was accompanied by a greater incidence and degree of cholesterol-induced atherosclerosis. On a diet of plain mash alone, pancreatectomized chicks exhibited spontaneous atherosclerosis similar in incidence and degree to that of unoperated controls. These depancreatized birds consistently exhibited normal plasma and tissue lipid levels. After 9 months, neither hypolipemia, hyperlipemia nor hepatic lipidosis developed. Blood glucose concentrations and glucose tolerance curves also remained at control levels throughout. These birds also failed to respond to ACTH. In summary, the altered pattern of lipids exhibited by depancreatized chicks fed cholesterol plus cottonseed oil and the accompanying altered incidence and degree of atherosclerosis suggest (despite the usual findings in birds fed plain mash) that the pancreatectomized chick has an altered lipid metabolism.

Use of the ballistocardiogram as a measure of the maximum force of cardiac contraction ISAAC STARR *Lab of Therapeutic Research, Univ of Pennsylvania, Philadelphia*

When the aorta and pulmonary artery of cadavers were injected in simulation of the cardiac contraction, the relative force imparted to the moving fluid can be calculated for any instant from the product of acceleration and an assumed mass. The values obtained can be compared with ballistocardiograms secured simultaneously. The spread of the ballistocardiogram, as measured by

the sum of the vertical depth of the I wave and height of the J wave is closely related to the maximal force developed during any 'systole' ($r = 0.93$, and 0.94 after correction for attenuation). The correlation between this maximum of force and the square root of I depth plus J height is not significantly different. The correlations with the areas of these waves are also significant, but both that with the area itself ($r = 0.67$) and that with the square root of the area ($r = 0.83$) are significantly inferior to 0.93 . Therefore, the maximal force exerted in any systole can be estimated from the ballistocardiogram with an accuracy the equal to that of many useful clinical methods. At present this estimation of the maximal cardiac force of any systole can be made only in relative terms, I have used the average value of healthy normal young adult males as a standard and determined the deviation of any subject from this value. Experiments leading to the estimation of cardiac force or power in absolute units are under way. Normal standards for the relative values have been constructed.

The effects of altitude on size, activity and composition of gases of the colon of dogs F. R. STEGGERDA AND T. C. BUNTING* *Dept of Physiology, Univ of Illinois, Urbana*

Into dogs' colons, made permanently opaque to x-rays, one end of an open tipped catheter tube was inserted 3-4 inches beyond the anal sphincter. The other end was attached by a T tube to an air recording pressure unit outside of the decompression chamber. By means of the other arm of the T tube samples of air could be inserted and withdrawn from the colon for analysis. A mounted x-ray tube and automatic cassette changer in the chamber provided an opportunity for taking pictures of the colon when desired. The results show that when 100 cc of air are injected into the empty colon of a 10 kilo dog breathing oxygen, there occurs a progressive increase in size and activity of the colon up to an altitude of 25,000 feet. The actual increase in both cases is about threefold. At altitudes approximating 25,000 feet and above there usually occurs an escape of the gas up into the small intestine. Room air remaining in the colon 20-45 minutes at 10,000 feet shows that the oxygen present is about 20% and carbon dioxide 4%. At 20,000 feet there is little change in this percentage composition, but at 25,000 feet occurs a consistent decrease in oxygen to about 15% and an increase in carbon dioxide to an average of 16%.

Further chronic toxicity studies of hydroquinone G. G. STERN,* S. LANG,* N. R. BREWER AND A. J. CARLSON *Physiology Lab, Univ of Chicago, Chicago, Ill.*

Additional data on the toxicity studies of hydro-

quinone in rats are presented. Three groups of 40 rats each were fed varying amounts of hydroquinone with citric acid and compared with a control group. After two years on test 7 control rats, 10 rats fed 0.1% hydroquinone plus 0.01% citric acid, 11 rats fed 0.5% hydroquinone plus 0.01% citric acid, and 20 rats fed 1.0% hydroquinone plus 0.01% citric acid were still alive. The data on body weight, tibial length, WBC, RBC, differential, revealed no significant differences.

Endocrine effects of electroconvulsive shock in the rat JAMES A. F. STEVENSON, SYLVAN J. KAPLAN AND H. ENGER ROSVOLD (introduced by JOHN S. NICHOLAS) *Lab. of Physiology and Dept. of Psychiatry, Yale Univ. School of Medicine, New Haven, Conn.*

Recent studies have emphasized changes in adreno-cortical function, and processes influenced by it, during electroconvulsive shock. The effect of a series of electroconvulsive shocks upon the adrenal and other endocrine glands in the male and female rat has been investigated. Following a series of 10 or 20 daily shocks (50 ma. for 0.2 sec.) the animals were killed 24 hours after the last shock. Controls were similarly treated except for the actual shock. In all experimental groups the mean weight of the adrenals was increased, the ascorbic acid concentration was not significantly different from that of the controls, indicating a true hypertrophy. The mean weights of the pituitaries and thyroids of the shocked animals showed a slight but persistent decrease. These changes were observed whether or not the animals lost weight during the shock treatment. The increase in adrenal size appeared to persist for at least one month after the last shock. Serum sodium concentration, and muscle water content were also measured. The relationship of these findings to studies of animal learning after electroconvulsive shock and to studies in the human after electroconvulsive shock are discussed.

Combined effect of anoxic anoxia and cocaine on dog blood sugar and hemoglobin J. CLIFFORD STICKNEY, DAVID W. NORTUP AND EDWARD J. VAN LIERE *Dept. of Physiology, School of Medicine, West Virginia Univ., Morgantown*

Cocaine, an epinephrine-potentiating-agent, when given to dogs subjected to 28,000 ft simulated altitude reduces the propulsive motility of the small intestine. It seemed of interest to determine whether cocaine would also potentiate other anoxic effects. Nine adult dogs, unanesthetized, and in the post-absorptive state, were given 15 mg/kg cocaine hydrochloride intravenously, were exposed for 15 minutes to 254 mm Hg barometric pressure (28,000 ft simulated altitude), or were subjected to a combination of the 2 pro-

cedures at weekly intervals. A second series of 8 dogs was similarly treated, except that 3 mg/kg cocaine were used. Blood sugar by the Folin-Wu and hemoglobin by the Sahli methods were determined on saphenous vein blood samples obtained immediately before and after the experimental procedures. Cocaine, alone, within 15 minutes increased blood hemoglobin concentrations by 10% (statistically insignificant) at both dosage levels, but did not affect blood sugar. Anoxic anoxia increased blood sugar by 26 and 29% ($P < 0.01$) and hemoglobin by 10 and 11% ($P > 0.20$ and < 0.01) in the 2 groups of dogs. Cocaine 15 mg/kg, plus anoxia, increased blood sugar 20% ($P = 0.017$) and hemoglobin 15% ($P = 0.07$) while 3 mg/kg, plus anoxia, caused increases of 20 ($P = 0.07$) and 13% ($P = 0.017$) respectively. Cocaine, thus, decreased slightly the blood sugar response to anoxia, while it increased slightly the elevation in hemoglobin concentration, but neither of these effects was statistically significant.

Studies on effect of anoxic anoxia on goat blood sugar J. CLIFFORD STICKNEY, DAVID W. NORTUP AND EDWARD J. VAN LIERE *Dept. of Physiology, School of Medicine, West Virginia Univ., Morgantown*

Goats, 3 female and 1 castrate male, were studied in regard to blood sugar and hemoglobin in jugular vein samples drawn after a 24-hour fast under control conditions and before and after 15-minute exposures at weekly intervals in a decompression chamber to a simulated altitude of 24,000 ft. Blood sugar was determined colorimetrically on Somogyi-Shaffer-Hartmann filtrates and hemoglobin by either the Sahli or the Andes-Northup colorimetric method. The average control blood sugar in the 4 goats was 60.6 (range 55-65) mg/100 ml. The average rise in blood sugar produced in a total of 10 exposures of the 4 goats for 15 minutes at 24,000 ft was 40.1 (range 29.3-60.5) mg/100 ml, which was significant at less than the 1% level. In 2 goats, exposures for 30 minutes to 24,000 ft produced rises that were about $\frac{1}{2}$ as great as for 15 minutes. Elevations in hemoglobin concentration produced by the anoxia were, on the whole, small, and their average, statistically, not significant.

Relation of vitamin B_{12b} to vitamin B₁₂ and the biological activities of these compounds E. L. R. STOKSTAD, T. H. JUKES, JOHN A. BROCKMAN,* J. V. PIERCE* AND H. P. BROQUIST* *Lederle Labs. Div. American Cyanamid Company, Pearl River, N. Y.*

Vitamin B_{12b} has been isolated from a fermentation product of *Streptomyces aureofaciens* as a red crystalline compound which exhibits different absorption spectra than vitamin B₁₂. Biological activities of vitamin B₁₂ and B_{12b} are the same.

for *Lactobacillus leichmannii* and for chicks. Catalytic hydrogenation of vitamin B₁₂ yielded a compound which possessed the same ultraviolet, visible and infrared absorption spectra and the same biological activities for chicks and *L. leichmannii* as vitamin B₁₂. These biological activities of the vitamin B₁₂ reduction product, described here, are in marked contrast to those of vitamin B₁₂, also produced by the hydrogenation of vitamin B₁₂ (KACZKA, WOLF, AND FOLKERS, *J Am Chem Soc*, 71 1514, 1949). Vitamin B_{12a} was reported to be approximately 10-30 % as active as B₁₂ for *L. leichmannii* and 30% as active for chicks. Evidence has been obtained which indicates that vitamin B₁₂ is involved in the methylation of homocystine to methionine in the chick. Chicks were placed on a ration composed of alcohol extracted soybean protein 25%, glucose 62.5%, cystine 0.2%, dimethylaminoethanol HCl, salts, corn oil plus vitamins A, D, and E, inositol, calcium pantothenate, niacinamide, riboflavin, pyridoxine, thiamine, pteroylglutamic acid, and biotin. On this diet, and in the presence of vitamin B₁₂, both homocystine and methionine were found to give a growth response. In the absence of vitamin B₁₂, only methionine gave a response while homocystine was without effect.

Coronary dilator activity of 1-(3',4'-dihydroxyphenyl)-2-isopropylaminoethanol (Isuprel) and other N-alkyl homologues of epinephrine O O STOLAND AND D L MARCHBANKS * *Dept of Physiology, Univ of Kansas, Lawrence*

The coronary flow was measured in dog heart-lung preparations and intact dogs. The rate of outflow was measured by a bubble flowmeter between the coronary sinus and the superior vena cava and the inflow by a flowmeter between the carotid artery and a coronary artery. Heart rate and blood pressures were simultaneously recorded. Doses of Isuprel, which lower the blood pressure and increase the heart rate, produced a fairly consistent increase in the coronary flow in the various experiments tried. Doses sufficient to cause coronary dilation markedly increased the heart rate in heart-lung preparations as well as intact animals. The Isuprel was obtained from the pharmacology department of Sterling-Winthrop Research Institute. A M Lands and others have shown that this drug is a vasodilator and bronchodilator. The therapeutic value of Isuprel as a coronary dilator would seem to us to be counteracted by the undesirable tachycardia which it develops.

Effect of tridione (3,3,5-trimethyl oxazolidine-2,4-dione) on the oxygen uptake of motor and sensory cortex of dog brain H C STRUCK, D L STUMPF* AND R J CAFFREY * *Dept of*

Physiology and Pharmacology, Creighton Univ School of Medicine, Omaha, Nebr

The effect of tridione on the oxygen uptake of dog cerebral cortex slices in Krebs-Ringer-Phosphate solution (dextrose substrate) has been studied by the Warburg technic to determine whether any difference exists in the response of the two areas to this drug. Dogs were stunned by a blow on the head, the brains removed within 2-3 minutes, and immediately placed in a moist-cold box. A total of 135 slices were obtained from motor areas and a similar number from sensory areas of 14 dogs, approximately equal numbers of slices being taken from each hemisphere. Half of the slices from each dog were placed in Ringer's solution, the other half in Ringer's solution containing 0.035 M tridione per liter. This concentration has been calculated to be within the pharmacologic range used *in vivo*. Oxygen uptake of the slices was then followed for 2 hours at 38°C using oxygen as the gas phase. The mean inhibition of oxygen uptake of the motor cortex by tridione was 9.3%, which is highly significant statistically. In contrast, the mean inhibition of all slices from the sensory cortex was 4.6%, approximately half that of the motor cortex. This is not significant statistically. These results indicate that the motor and sensory areas of the dog cortex differ in their response to this anticonvulsant drug.

Abnormal electrocardiograms of chickens produced by potassium deficiency and effects of certain drugs on the abnormalities PAUL D STURKIE *Lab of Avian Physiology, Rutgers Univ, New Brunswick, N J*

Twenty-two White Leghorn chicks were placed on a potassium-deficient ration at 4 days of age. Seven showed abnormal ECG's after 10 to 12 days and within 21 days most of them showed abnormalities or were dead. Seven chicks showed some form of second degree AV block and 5 showed complete AV block. Two exhibited SA block or sinus slowing, one premature ventricular systoles and the diagnosis of two was in doubt. Some of the birds showed more than one abnormality. Ten birds, 6 weeks of age, were placed on the K-deficient ration. All of them showed abnormal ECG's within 18 days and some as early as 10 days. Nine of the 10 birds showed in one or more of their ECG's premature systoles. One of the birds exhibited second degree AV block. Eight young chicks and 3 older birds which showed abnormal ECG's received diethylaminoethanol intramuscularly. The abnormalities included second degree AV block, complete AV block, premature systoles and possibly SA block or sinus slowing. In every case, the ECG's reverted to normal. Procaine was also administered intramuscularly to 5 birds with abnormal ECG's. It

was effective in only one case Atropine sulfate was effective in 4 cases out of 6 in reverting the ECG's to normal

Relative effectiveness of natural estrogens in stimulating early uterine growth CLARA M SZEGO *Dept of Zoology, Univ of California, Los Angeles*

The relative effectiveness of estrone, estradiol and estriol in promoting early uterine growth has been determined in immature female rats after intraperitoneal injection, and in adult ovariectomized females following intravenous administration of these compounds In both preparations the order of activity was estriol > estradiol > estrone In the immature rat, the relative effectiveness was as follows in oil estriol, 100, estradiol, 39, estrone, 7, in saline estriol, 100, estradiol, 19, estrone, 2.4 These data contrast sharply with results obtained when other criteria of estrogenic activity are employed Thus, by the vaginal smear technique, estriol is the least active of the 3 natural estrogens The effectiveness of estrone and estradiol by the uterine water method of assay appeared to be relatively independent of the vehicle used over the entire dosage range studied In contrast, estriol was found to be about 3 times more effective in stimulating the infantile rat uterus when administered in saline medium than in oil A significant response was obtained with 0.003 μ gm of estriol in saline/animal This observation is in line with a) the relatively greater solubility of estriol in aqueous media, and b) the peculiar sensitivity of the infantile rat uterus to stimulation by this estrogen Application of these results to the assay of estrogens isolated from biological fluids is discussed

***In vitro* and apparent *in vivo* solubility of acetylene**

HENRY LONGSTREET TAYLOR AND CARLETON B CHAPMAN * *Lab of Physiological Hygiene, Univ of Minnesota, Minneapolis*

It is recognized that the acetylene method gives cardiac output values about 25% below those from the direct Fick catheterization method Since the theory of the foreign gas method has not been questioned, the discrepancy between these methods must be related to acetylene solubility, recirculation and effects of rebreathing Thirty-two measurements of acetylene solubility in human blood at 37.8°C and partial pressures of 7.4 to 118.0 mm Hg were made The solubility of C_2H_2 in blood at 37.8°C and 760 mm Hg was found to be 700.19 ± 2.64 instead of the Grollman value of 740 This changed solubility accounts for 5% of the difference between the two methods The recirculation error was evaluated with 19 simultaneous determinations of CO by the catheterization and acetylene procedures Acetylene was determined in the mixed venous blood at inter-

vals between 5 and 40 seconds of rebreathing and it was found that recirculation of acetylene accounts for another 5% of the discrepancy It was further found that during rebreathing the arterial oxygen content increased by 0.28 vol % Since it has been shown that venous oxygen saturation does not change during rebreathing, failure to allow for this introduces an error of not more than 7% The apparent *in vivo* solubility of acetylene calculated by equating the corrected acetylene data with the catheterization output gives an apparent solubility of acetylene *in vivo* which is 10% less than that *in vitro* This discrepancy may be explained by a) a diffusion gradient between alveolar air and blood or b) failure to account for all the errors in the acetylene method

Effect of polarization on conduction velocity of frog nerve and its modification by KCl ROBERT E TAYLOR (introduced by H A BLAIR) *Dept of Physiology, Univ of Rochester, Rochester, N Y*

The effects of polarizing currents on the conduction velocity of nerve have been investigated The most excitable A fibers of the sciatic-peroneal nerve of the frog were studied and measurements were made after the initial transient and before any appreciable long time effects of current flow had occurred Current, applied longitudinally and increasing linearly with distance for 5 cm along the nerve, results in an applied transverse membrane current which is virtually independent of distance except near the ends of the chamber, and produces a region of constant polarization about 3 cm long For any given amount of polarizing current the velocity of conduction is constant throughout this region The curve of velocity versus polarizing current has its maximum at weak cathodal currents, falling away on either side until blocking occurs at about $\frac{1}{2}$ the normal velocity Relief of KCl block by anodal polarization does not restore the velocity to the normal unpolarized value, but to about the value shown by normal nerve subjected to a comparable polarization The complete mathematical solutions for the usual core conductor model and for a saltatory model have been derived The steady state value of the membrane current in the midportion of the chamber is almost independent of distance, and completely independent of the membrane impedance in so far as it may be represented by a linear passive network

Effect of section of the corpus callosum on experimental convulsions R D TEASDALL* AND G W STAVRAKY *Dept of Physiology, Faculty of Medicine, Univ of Western Ontario, London, Canada*

It was previously shown that partial isolation of spinal neurones increases their irritability (Cannon, 1939, Stavrakys, 1943, Drake and Stav-

raki, 1948, Tersdall and Stavray, 1948, *et al*) It seemed interesting to ascertain whether partial denervation would have the same effect on the highest levels of the central nervous system. With this in mind, in 20 cats the corpus callosum was aseptically cut and after recovery from operation the animals were periodically convulsed with metrazol. Beginning 6-9 months after the operation the threshold of the animals to convulsant doses of metrazol was diminished by 20 to 50% and the convulsive pattern was altered in a characteristic way. In normal cats metrazol produces a clonic-tonic-clonic convulsive sequence. This sequence was maintained after section of the corpus callosum but the duration and the severity of the clonic phases of the convulsion was greatly increased. After 4 months of weekly injections of metrazol the corpus callosotomized animals became partially refractory to small doses of both metrazol and acetylcholine, this depressed state lasting for about 3 months. The sensitivity of normal control cats became increased instead of being depressed after a similar 4 month period of weekly injections of metrazol. The observed changes in the susceptibility to metrazol and to acetylcholine convulsions and in the convulsive pattern which occurs after section of the corpus callosum are attributed to the sensitization of the cerebral cortical neurones, which taken place following section and degeneration of the commissural fibres joining the cerebral hemispheres.

Effects of purified hypophysial gonadotrophins on the cholesterol ester content of rat testis

JAY TEPPERMAN, HELEN M. TEPPERMAN* AND JANET M. DEWITT. *Dept. of Pharmacology, Syracuse Univ. College of Medicine, Syracuse, N. Y.*

In a previous study (*Endocrinology* 41: 187, 1947) it was shown that injection of mixed gonadotrophins of sheep pituitary origin (Gonadophysin, Searle) resulted in an increase in testis cholesterol ester per 100 gm. of rat. A commercial chorionic gonadotrophin (Follutein, Squibb) was without effect on this parameter in untreated rats, but in Gonadophysin primed animals Follutein injections produced a reduction in testis cholesterol ester in association with enhanced androgen production. The suggestion was made that some constituent of Gonadophysin, possibly FSH, was responsible for the cholesterol ester increase. On the basis of studies with purified hypophysial gonadotrophins (prepared by McShan and Meyer) it is now possible to state that FSH has no apparent effect on the absolute amount of testis cholesterol ester whereas two purified pituitary LH preparations have consistently yielded the type of cholesterol ester increase seen following Gonadophysin administration. These studies were made on intact weanling rats as well as on male rats implanted with stil-

bestrol pellets according to the technique of Nalbandov and Baum (*Endocrinology* 43: 37, 1948).

Temperature and convulsive activity. PAUL TESHCHAN* AND E. GELLHORN. *Lab. of Neurophysiology, Dept. of Physiology, Univ. of Minnesota, Minneapolis*

The effect of heating a part of the cerebral cortex was studied comparatively on convulsive and nonconvulsive cortical areas of the cat. The animals were anesthetized with dial-urethane and the convulsive potentials were induced by topical application of picrotoxin. Results were as follows: 1) Convulsive potentials disappear at a lower temperature (in experiments involving progressively increasing temperatures) or earlier (in experiments in which the elevated temperature was kept constant) than normal potentials. Before the spike potentials disappear they show in most experiments a progressive decrease in amplitude and frequency. This increased sensitivity of the convulsive neuron is thought to be the result of the combined action of increased temperature and convulsive activity on the metabolism of the neuron. This interpretation accounts for the great similarity between these experiments and the earlier work of Gellhorn and Heymans on the action of anoxia on convulsive potentials. 2) Under the combined effect of elevated temperature and topically induced convulsive activity (A) more neurons are damaged than under the influence of heat on normal neurons (B). This is indicated by the fact that on recovery the amplitude of the remaining normal potentials is much less under A than under B and also that application of a convulsant drug after heating evokes spikes of higher amplitude and frequency under B than under A. 3) Repeated heating at short intervals to a moderately increased temperature (44-46°) is accompanied by a marked increase in frequency of convulsive discharges with each heating. However, this excitatory effect declines gradually as does the amplitude of the spike potentials.

Discrimination of weights by men with penetrating lesions of parietal lobes. HANS-LUKAS TEUBER*, MORRIS B. BENDER AND WILLIAM S. BATTERSBY*. *Psychophysiological Lab., Dept. of Neurology, New York Univ., College of Medicine, New York City*

Ability to judge lifted weights was analyzed in 16 men with history, surgical and x-ray evidence of loss of brain substance in the parietal regions. These men were drawn at random from a list of 250 veterans of World War II with gunshot wounds of the brain. Discrimination of weights was tested by the method of constant stimuli. Each subject compared a standard weight with another weight

by successive lifting with the unsupported hand. Twenty different weights were used. Thresholds of discrimination based on a minimum of 200 judgments were obtained separately for right and left hand. Results showed that ability to judge lifted weights may be unimpaired in men with trauma of parietal regions, as long as there are no signs of motor deficit. That is, thresholds obtained separately for the hand contralateral to the cerebral lesion were not significantly different from thresholds obtained for the other hand, nor were they different from thresholds obtained in normal controls. This was true even for cases in which other somatosensory functions, such as two point discrimination, were found to be impaired on the side opposite to the trauma. However, thresholds based on simultaneous lifting of one weight in each hand were significantly different from those obtained in normal controls. Under these conditions, the patients consistently underestimated the weight held in the affected hand. The significance of these results for theories of sensorimotor function is discussed.

Semi-automatic recording of electrical skin resistance patterns PRICE E THOMAS* AND IRVIN M KORR *Kirksville College of Osteopathy and Surgery, Kirksville, Mo*

In recent years electrical skin resistance (ESR) explorations have found considerable application in experimental and clinical investigation. In our laboratories ESR patterns on the human trunk have been segmentally correlated with other factors (*Federation Proc* 7 67, 1948, 8 87, 1949). The simple device herein described permits rapid, almost automatic explorations, with photographic recording of the ESR patterns, and eliminates many artefacts inherent in 'hand' exploration. The needle movement of a modified microammeter is used to actuate the variable arm of an electrolytic rheostat. The current passed by this circuit is of sufficient magnitude (0-800 ma AC) to vary the brightness of a 6V lamp proportionately to the microammeter readings (0-50 μ a). The bulb is housed over the exploring (roller) electrode and illuminates a rectangle identical in size and shape with the area of electrode contact. This assembly, supported from a rail, is propelled in the long axis of the body by a constant-speed motor. At the end of each strip the assembly is moved laterally the width of the electrode by means of a pawl and notch arrangement, and the motor is reversed for the next strip. The explorations are conducted in a dimly illuminated room with camera-shutter open throughout. Thus, strips of light are photographed which vary in brightness according to ESR variation in corresponding strips of skin. An outline of the subject's body and any bony landmarks previously marked on his

skin, appear on the same film in accurate relation to the record. A calibration strip is also recorded.

Functional connections between hypothalamus and medulla W C THOMPSON* AND L M N BACH *Depts of Physiology and Psychiatry and Neurology, Tulane Univ School of Medicine, New Orleans, La*

Studies were carried out on the effects of medullary lesions upon hypothalamically induced alterations in blood pressure, respiration, and knee jerk. Cats, anesthetized with sodium pentobarbital (Nembutal), were stimulated by electrodes oriented stereotaxically in the posterior hypothalamus. Lesions were placed in various parts of the medullary reticular formation by stereotaxically directed electrodes in an attempt to alter the recorded responses. Several points in the mid-brain and posterior hypothalamus were mapped which, when stimulated, usually produced simultaneous enhancement or depression of blood pressure, respiration, and the knee-jerk. Stimulation of the medial inhibitory reticular formation of the medulla contraverted the usual vasopressor response resulting from simultaneous stimulation of the posterior hypothalamus in a consistent but limited fashion. Lesions placed in the medial inhibitory reticular formation of the medulla caused enhancement of the hypothalamically induced effects on the 3 functions whereas when the intactness of the lateral facilitatory reticular formation was destroyed, the hypothalamically induced enhancement was depressed or abolished. These results indicate that the hypothalamic facilitation or inhibition of the knee-jerk acts in a parallel manner on blood pressure and respiration and that these effects are mediated by the lateral facilitatory reticular formation and the medial inhibitory reticular formation of the bulb respectively.

On electrically induced optical and structural changes in certain nerves and Elodea cells JULIAN M TOBIAS AND SIDNEY SOLOMON * *Dept of Physiology, Univ of Chicago, Chicago, Ill*

Whole nerve polarization (continued or tetanic) (crayfish, lobster, frog) causes anodal shrinkage, increased opacity and probably increased rigidity, and cathodally causes swelling, increased transparency and increased surface stickiness. These changes are reversible, re-reversible etc., slowly on standing and more rapidly following polarity reversal. The phenomenon, though visible, has been photometrically objectivized and quantified. It occurs with either platinum or non-polarizable, wick electrodes, with the nerve in mineral oil, Ringer or moist air. As opacity increases anodally, light scattering also increases there, suggesting particle or fiber size change. Calcium ion excess inhibits, and potassium ion excess may accentuate

the electrically induced change. Calcium ion excess, independently of any impressed electrical field, increases nerve opacity whereas potassium ion seems to increase transparency. There is evidence that nerve water moves toward the cathode. Polar peculiar changes in size and configuration are also seen in single frog nerve axons. Experiments are in progress to determine the relationship, if any, of these phenomena to propagated impulses. Measurements of changes in nerve viscosity as a function of activity are also being made, in terms of damping of high frequency sound transmitted along the nerve long axis (collaborating with William Fry and Frank Fry, Dept of Electrical Engineering, Univ of Illinois). Using Brownian movement as a viscosity measure, it has been found that polarization increases viscosity of the hyaline, cytoplasmic matrix in *Elodea* cells, anodally. This change too is reversible. It is felt that these findings may reflect changes in protoplasmic structure which underlie excitation.

Distribution and assay of inhibitors and accelerators of blood coagulation in extracts of organs of normal and hemophilic man L. M. TOCANTINS AND R. T. CARROLL * *Dept of Medicine, Jefferson Med College, Philadelphia, Penna*

Portions of tissues removed from the bodies of the 2 subjects within 2 hours after death, were washed free of blood and dried with acetone. The powders from each organ were extracted in pairs (one normal and one hemophilic) with absolute methanol, ethyl ether or 0.85% NaCl and the respective extracts were assayed against standard human brain thromboplastin, cephalin, thrombin and lipid antithromboplastin preparations, using silicone contacting surfaces and stable normal human plasma as substrate. The relative content of antithromboplastin in the tissues from both subjects was in the following order: brain (highest), adrenal, liver, spleen, lung, heart, tongue, kidney, pancreas, skeletal muscle, testes, duodenum, pituitary, colon, diaphragm, thyroid, skin (lowest). Chief differences in antithromboplastin content (units gm of tissue) between normal and hemophilic tissues: Testes normal 25, hemophilic 59, skeletal muscle normal 37, hemophilic 56, Brain normal 1145, hemophilic 1644, Heart normal 72, hemophilic 93. All hemophilic tissues assayed greater unitage of antithromboplastin than normal tissues, excepting the lung, in which the difference between the 2 extracts was non-significant. The most potent thromboplastins were obtained from saline extracts of brain. Lung and kidney extracts were less potent. Extracts of these hemophilic organs had essentially the same thromboplastic activity as those of normal organs. Normal skeletal muscle behaved as thrombo-

plastin, while hemophilic skeletal muscle had antithromboplastin, but no thromboplastin activity. Cephalin fractions extracted from brain and lung of the 2 subjects had about equal potency as clot accelerators. Antithrombins were found in normal and hemophilic testes and in normal pancreas.

Effect of lymphatic necrosis on neuro-muscular function (action potential, acetylcholine synthesis) of hypophysectomized animals CLARA TORDA AND HAROLD G. WOLFF *New York Hospital, Kingsbridge Hospital (V A), and Depts of Medicine and Psychiatry, Cornell Univ Med College, New York City*

In the absence of the adrenocorticotrophic hormone of the pituitary gland (ACTH) in hypophysectomized animals the neuro-muscular function is impaired. Two measurable components of this dysfunction are a decline of action potential during repetitive stimulation of the nerve and a decrease of acetylcholine synthesis. Both the action potential and the acetylcholine synthesis return to normal during the injection of ACTH to hypophysectomized animals. Since the decline of action potential and acetylcholine synthesis found in myasthenia gravis can be counteracted by either administration of ACTH or removal of the thymus it became of interest to investigate whether removal of lymphoid tissue of hypophysectomized animals restores the function of the neuro-muscular system to normal. Hypophysectomized rats were either injected with nitrogen mustard or exposed to x-ray treatment. After significant necrosis of the lymphoid tissue occurred action potential measurements and acetylcholine synthesis tests were performed. Necrosis of the lymphoid tissue did not restore the action potential and the acetylcholine synthesis to normal levels. Although the possibility that the negative results are the outcome of general debilitation due to combined hypophysectomy and nitrogen mustard and x-ray treatment cannot be excluded, the results suggest that the effect of ACTH in restoring the neuromuscular function of hypophysectomized animals is due to a mechanism other than a simple reduction of the mass of lymphatic tissue.

Effect of altered breakfast habits on physiologic response W. W. TUTTLE AND KATE DAUM * *Depts of Physiology and Nutrition, State Univ of Iowa, Iowa City*

An experiment involving 10 women was performed to show the effects of various breakfast patterns on physiologic response. The subjects lived in a University dormitory and ate all their meals in the hospital dining room supervised by the Department of Nutrition. The breakfast patterns employed were 1) basic breakfast repre-

senting approximately one-fourth the total daily caloric requirement (600 Cal), 2) light breakfast (270 Cal), 3) heavy breakfast (1000 Cal) and 4) 'no breakfast' Responses studied were 1) neuromuscular tremor magnitude, 2) capacity to do work, 3) choice reaction time and 4) strength endurance Each breakfast pattern lasted 5 weeks Comparison of data collected twice weekly for each breakfast pattern justified the following conclusions No differentiation by way of tremor magnitude, capacity to do work, choice reaction time or strength endurance could be established following regular consumption of heavy and light breakfasts respectively, of ordinary breakfast items In comparison with omission of breakfast, consumption of a 600 Cal breakfast consisting of fruit, breakfast cereal, milk, sugar, toast and butter resulted in a significant reduction of tremor magnitude in all cases, choice reaction time in 60% of the cases and an increase in maximum work output in 80% of the cases during the period when food was consumed at breakfast time Strength endurance was unaffected

Effect of water diuresis on electrolyte excretion in normal man JOHN R. URBACH, M. D. PHELPS, WILLIAM A. STEIGER, HARRY GOLD AND SAMUEL BELLET (introduced by PAUL R. DUMKE) *Heart Station, Philadelphia General Hospital and the Robinette Foundation, Univ of Pennsylvania, Philadelphia*

Reports on the effect of water diuresis on excretion of urinary solutes conflict Upon reinvestigation significant changes were found Preliminary work was done on dogs, definitive experimentation on 3 normal humans Endogenous creatinine clearances were obtained as relative measure of glomerular filtration, since exogenous clearance techniques exerted effects of their own Creatinine, chloride, phosphate, urea, CO_2 content, sodium, and potassium determinations were done on blood and urine, pH on urine only After several control periods, diuresis was induced with distilled water (50 cc/kg) by stomach tube, and excretion of these constituents measured at regular intervals Glomerular filtration varied only slightly and small variations in plasma concentration of solutes did not influence their excretion Total CO_2 excretion was directly proportional to urine flow (each expressed as clearance ratios), with high statistical correlation ($r = 0.846$) Since pH did not vary with diuresis or CO_2 excretion, the bicarbonate fraction also increased, but neither sodium nor potassium rose concomitantly Sodium and chloride excretion paralleled each other but did not appear to be related to any other factor Potassium excretion also varied, and U/P ratios below one were obtained, but again no constant correlation with any other variable could

be found Urea clearance remained constant in 2 human experiments, and varied markedly in the 3rd Phosphate excretion did not vary significantly

Effect of acclimatization on motility of small intestine during anoxia EDWARD J. VAN LIERE, J. CLIFFORD STICKNEY AND DAVID W. NORTHUP *Dept of Physiology, West Virginia Univ School of Medicine, Morgantown*

It has been shown in our laboratory that the propulsive motility of the small intestine in rats is decreased by anoxic anoxia It was reasoned that if rats were acclimatized to low oxygen tensions, exposure to altitude would no longer produce this effect A group of 17 albino rats was acclimatized by subjecting them for 3 hours, on the average, each day to a pressure of 303 mm Hg (simulated altitude of 24,000 ft), 8 were exposed for 26 and 9 for 62 days These acclimated rats were paired with normal rats (unacclimated) which were as nearly alike in weight and age as possible They were fasted for 24 hours A pair of these rats was given 2 cc of a charcoal-acacia mixture by stomach tube After allowing 10 minutes for some of this material to enter the small intestine, both rats were placed in a low-pressure chamber at a pressure of 254 mm Hg (simulated altitude of 28,000 ft) At the end of 30 minutes they were removed from the chamber and decapitated The small intestine was removed, slit open and the distance the charcoal had traversed it measured It was observed that the propulsive motility was significantly less in the unacclimatized than in the acclimatized animals This was interpreted to mean that the effect of anoxic anoxia on the propulsive motility of the small intestine could be used as another criterion for acclimatization

Metabolism of I^{131} during acute adaptation to anoxia LESTER VAN MIDDLESWORTH *Dept of Physiology, Univ of Tennessee College of Medicine, Memphis*

Rats fed a stock diet and a low iodide diet have been rapidly adapted to severe anoxia by exposure to 258 mm Hg barometric pressure (equivalent 27,000 ft altitude) at 11–14°C for 2–4 hours After this exposure the low iodide rats were injected intraperitoneally with 10 microcuries of carrier-free I^{131} The barometric pressure was then reduced to 177 mm Hg (equivalent 35,000 ft altitude) for 8–12 hours Urine collections were made throughout the exposure The animals were then returned to sea level, blood samples withdrawn and thyroid glands excised Plasma proteins were precipitated with $\text{BaOH}-\text{ZnSO}_4$ reagents and the radioactivity of precipitate and filtrate determined separately The thyroid glands were digested in 2 N NaOH and an aliquot was analyzed for I^{131}

while another aliquot was neutralized, extracted with normal butyl alcohol and the alcohol solution submitted to 2-dimensional paper chromatography with 2,4,6 collidine-2,4 lutidine—water and butyl alcohol—ammonium hydroxide solvent mixtures. Suitable sea level control rats were similarly studied with I^{131} . Animals adapted to severe anoxia demonstrated less than 2% of plasma I^{131} in protein-bound fraction, while 20–30% of plasma radioactivity was in the protein-bound fraction of controls. The thyroid glands of the anoxic series contained only $\frac{1}{2}$ as much radioactivity as controls. Radioautographs of the paper chromatograms demonstrated at least 7 radioactive compounds in the anoxic thyroid hydrolysates, but the quantity of all these compounds appeared to be less than that shown in similar chromatograms made from thyroids of control rats.

Protein metabolism of fracture callus and muscle trauma studied with radioactive methionine
LESTER VAN MIDDLESWORTH *Dept of Physiology, Univ of Tennessee, Memphis*

Rats on a high and a low protein diet (27% and 8% casein, respectively) were subjected to standard fractures of one fibula and a 1.5-inch incision produced and sutured in the abdominal musculature. After 7 days 7 mg of radioactive methionine (4×10^7 counts/min), furnished by D. L. Tabern of Abbott Laboratories, was injected intraperitoneally. After 4 additional days the animals were killed. Analyses were made for radioactive sulfur and for nitrogen in the muscle scar, normal muscle, fracture callus and normal fibula. Results were then expressed as S^{35}/N . The S^{35}/N in normal tissues of the low protein animals was 1.5 to 3.3 times greater than in rats on the high protein diet. This is possibly referable to the isotope dilution offered by greater methionine content of the high protein diet. Muscle trauma had healed well in high and low protein groups. Muscle trauma of the low protein cases showed twice the concentration of S^{35} shown by normal muscle tissue of low protein rats. However, the high protein rats showed no localization of S^{35} in the muscle scar tissue. Fracture healing was quite different, the high protein rats had 10 times more S^{35} in the fracture callus than in unfractured fibula and the callus was well formed. The low protein animals showed negligible healing of the fracture and no localization of S^{35} in the fracture scar. It therefore appears as though more dietary protein was necessary for healing of the bone fracture than for healing muscle trauma.

Acceleration of growth with early sexual development in the female monkey (*Macaca mulatta*)
G. VAN WAGENEN *Dept of Obstetrics and Gynecology, Yale Univ School of Medicine, New Haven, Conn*

cology, Yale Univ School of Medicine, New Haven, Conn

Androgen treatment of the young male rhesus monkey induced early bone union of the skeleton, an increase in muscular development and precocious spermatogenesis (VAN WAGENEN, *Federation Proc* 6: 219, 1947). It has now been possible to double the growth rate and reduce, by half, the age of the young female monkey at time of menarche (first menstruation). In a monkey colony of 5 generations, the average age at menarche is about two years, when the weight is around 3500 grams. Crystalline testosterone propionate dissolved in vegetable oil was given intramuscularly to two young monkeys weighing 1410 and 1600 grams. The dosage was 7.5 mg/kg/week. Injections began at 5 months, inducing an immediate rise from the normal curves for body-weight and length. At one year the treated animals reached the weight and length of two-year-olds and menarche occurred exactly at the end of a year in one animal and at one year, 19 days in the other. Androgen was then discontinued. This was a true beginning of sexual maturity and not just a spurious bleeding because 6 and 7 menstrual cycles, irregular as typical of adolescence, have followed, accompanied by the external skin changes characteristic of the maturing monkey. This great augmentation of growth with differentiation has not been analyzed. One is inclined to interpret it as a generalized increase in protein anabolism brought about by the nitrogen and salt retention effect of the hormone but the release of hypophyseal hormones or some other intervening mechanism may be involved.

Sensitivity of x-rayed animals to infusion of histamine, adenosine and trypsin
K. D. VENTERS* AND E. E. PAINTER *Univ of Illinois, College of Medicine, Chicago, Ill*

Control and x-rayed rabbits and dogs given an LD₅₀ dosage have been infused in the manner described previously (*Federation Proc* 7: 90, 1948) and 'threshold values' have been established for exogenous histamine, adenosine and trypsin. It appears that sensitivity of rabbits to adenosine is not increased after radiation, but sensitivity to histamine increases markedly. Maximal changes in sensitivity are directly correlated with other physiological findings occurring at the same time after radiation and must be a function of damage of tissue. Marked susceptibility of x-rayed rabbits to trypsin has made it impossible to record changes with this substance. It is apparent from the table below that dogs show their maximal increase in sensitivity to all 3 substances (approximately 50% change) at 2–2½ hours after x-radiation. These findings are correlated exactly in time with the main clinical sign of vomiting in the dog.

Our studies suggest that more than one breakdown product may be involved in the early biochemical disturbance to account for the symptoms of radiation sickness

Threshold Values for Maintaining 5.8 mm Hg Drop in Blood Pressure

Control rabbits		Post radiation in hours				
		1	1½	2	2½	3
		<i>ugm/kg/min</i>				
Histamine	6.7 (14)	7.0	3.1	2.0	2.2	2.7
Adenosine	111.2 (12)	119.0	192.0	208.0	281.0	188.0
Trypsin	107.0 (10)	No threshold could be established after radiation				
Control dogs		Post radiation				
		<i>ugm/kg/min</i>				
Histamine	1.2 (17)	1.0	0.6	0.5	0.4	1.1
Adenosine	120.4 (21)	94.0	81.2	81.4	93.0	118.0
Trypsin	113.2 (16)	96.0	89.0	55.3	49.3	73.0

Anti-ulcer action of estrogen in experimental animals FRANK E. VISSCHER AND ADRIAN P. TAZELAAR * *Labs of the Upjohn Company, Dept of Pharmacology and Endocrinology, Kalamazoo, Mich*

The incidence of peptic ulcer is greater in men than in women by a factor of about four, while in human pregnancy peptic ulcer is rarely, if ever, seen. These observations suggest that estrogen may have an anti-ulcer action. Such action has been demonstrated in two experiments on starvation ulcers in male rats. The degree of rumenal ulceration was greater in groups of 8 male rats receiving, as pre-treatment, subcutaneous injections of estrone, 200 γ in an aqueous suspension per week for three weeks. The anti-ulcer action was not evident at 40 γ estrone per week nor with 200 γ estrone and 2 mg progesterone in combined dosage, per week. Rats showing anti-ulcer action of estrogen grew less rapidly as compared with control rats and with rats not benefitted by estrogen. Results of paired feeding experiments on rats receiving 200 γ estrone per week, and results with other estrogens will be reported.

Subharmonics generated in ears of humans and animals at intense sound levels HENNING E. VON GIERKE (introduced by H. O. PARRACK) *Aero Med Lab, Air Materiel Command, Wright-Patterson Air Force Base, Dayton, Ohio*

Subjective undertones have never been found at usual sound levels although many investigators searched for them. We discovered that subharmonics are heard by subjects exposed to sound intensities above 140 db ref 0.0002 dynes/cm².

The frequency of the subharmonic was exactly one-half the frequency of the stimulating signal and its loudness was 70 db below an exposure signal of 9 Kcps. The subharmonic was radiated from the subject's eardrum and its level measured outside the auditory canal was 60 db below the stimulating signal. This proves the subharmonic is generated mechanically in the middle ear. Other tones, lower in pitch and loudness, were sometimes heard. Discomfort and possible hazard to hearing limited observations on humans to 2 frequencies. From the ears of anesthetized guinea pigs subharmonics were radiated at exposure frequencies from 3.5 to 23 Kcps. Other sounds, sometimes not harmonically related to the fundamental, were observed at frequencies and intensities below the subharmonic. A subharmonic becomes measurable at the guinea pig ear at an exposure level of 95 db at 9 Kcps and is 50 db below the fundamental. With increasing exposure level the subharmonic increases more rapidly, becomes unstable or interrupted above 115 db exposure level, and becomes a crackling or fluttering noise above 135 db. Subharmonics have also been produced by the ears of rats, cats, and dogs. These observations may be important to theories of middle ear mechanics and to an explanation of the behavior of the human ear in intense sound fields.

Conduction velocity of ulnar nerve in human subjects of different ages and sizes IRVING H. WAGMAN AND HENRY LESSE * *Dept of Physiology, Jefferson Med College of Philadelphia, Philadelphia, Penna*

Conduction velocity measurements of the most rapidly conducting ulnar nerve fibers supplying muscles of the hypothenar eminence were made on human subjects whose ages ranged from 3 to 80 years. The measurements were made by recording muscle action potentials obtained by percutaneous stimulation of the nerve at two points, namely, the wrist and the elbow. Results show that the maximum velocity of these nerve fibers found in adults (average = 59 meters/sec for a group ranging in age from 20 to 35 years) is attained as early as the third year of life. This bears out histological studies of Rexed (*Acta Psych Neurol Suppl* 33, 1944) who showed that in the human the ventral roots reach full development between the ages of 2 and 5 years. From the present functional measurements, it is shown that the time consumed by the motor impulse in traveling from the spinal cord to the periphery increases as the individual grows. It is also demonstrated that this time utilized by the motor impulse is less in small than in large individuals of the same age. As a consequence similar considerations may hold true for total reflex time. The present analysis

points to the size of the individual as the main factor determining the relations discussed here. However, from a limited number of measurements obtained on persons past 60 years of age, it seems that there may be a slowing of conduction velocity in old age and, therefore, a resultant lengthening of reflex time.

Interruption of bulbocapnine catalepsy in rats by environmental stress HENRI N. WAGNER, JR. AND JAMES W. WOODS (introduced by CURT P. RICHTER) *Psychobiological Lab., Phipps Psychiatric Clinic, and the Dept. of Physiology, Johns Hopkins School of Medicine, Baltimore, Md.*

Since 1910 considerable attention has been focused upon the effects of the drug, bulbocapnine, which experimentally produces in animals practically all of the motor manifestations seen in human catatonia. Several studies have been made in this laboratory to determine by what means the catalepsy of bulbocapnine can be abolished, with the hope that the information obtained might be of therapeutic importance to man. Previous studies by one of us have shown that, although cataleptic as a result of injection of bulbocapnine, monkeys, cats and rats remain alert to sensory stimuli of all types, vision and hearing in particular have been studied with the use of conditioned galvanic skin responses. The animals thus are in rapport with their environment but are unable to move. In this respect the animals under bulbocapnine resemble human catatonic patients, in whom a rapport with their environment has frequently been demonstrated. In this report we have described the finding that various stressful environmental factors, namely, intensive auditory stimulation, electric shocking in a situation which results in vicious fighting, and the immersion of the animals in deep water, result in a transient but complete disappearance of the cataleptic state. During the periods of stress, most of which may be considered life-threatening situations, the rats behaved in a manner indistinguishable from that of normal animals under the same circumstances.

Effects of dicumarol on peripheral circulation in patients with vascular disease KHALIL G. WAKIM, MARTIN S. KLECKNER, JR.,* NELSON W. BARKER* AND WALTER F. KVALE* (with the technical assistance of ADRIEN N. PORTER*) *Mayo Clinic, Rochester, Minn.*

From their experimental work on animals and on the empty beating heart, Gilbert and Nalefski (*Proc. Central Soc. Clin. Research* 21:5, 1948) concluded that dicumarol has a definite effect on blood flow and that the favorable results in cases of coronary occlusion are primarily due to

the action of dicumarol in increasing the coronary blood flow. We are studying by means of the venous occlusion plethysmograph with the compensating spirometer recorder and by use of cutaneous thermocouples the effects of dicumarol on the skin temperature and on the blood flow in the extremities of patients who are receiving the drug for anticoagulant therapy. After the establishment of controls, dicumarol is administered orally in therapeutic doses for several days, during which blood flow and cutaneous temperatures are recorded and compared with the control values. So far, our findings in 5 cases of arteriosclerosis obliterans consistently indicate that even though dicumarol produces a significant prolongation in the plasma prothrombin time, the accompanying changes in cutaneous temperatures over several regions of the body and in blood flow in the upper extremities are insignificant. However, there was a slight but statistically significant reduction rather than increase in blood flow in the lower extremities.

Effect of epinephrine and nor-epinephrine on whole blood coagulation JEROME M. WALDRON (introduced by I. J. PINCUS) *Dept. of Physiology, Jefferson Med. College, and Division of Medicine, Pennsylvania Hospital, Philadelphia*

Previous investigators have stated that epinephrine *in vivo* accelerates whole blood coagulation but that epinephrine *in vitro* had no effect on blood coagulation. All of these investigations had been performed in glass tubes. This problem was reinvestigated by measuring the coagulation time of fresh whole blood in collodion lined tubes. Very dilute solutions of epinephrine were added *in vitro* or injected intravenously. In addition, the effect of nor-epinephrine *in vitro* and *in vivo* on the coagulation time of fresh whole blood was investigated. Both epinephrine and nor-epinephrine *in vitro* accelerate the coagulation time of human and canine fresh whole blood. A dilute solution of nor-epinephrine when injected intravenously in dogs also accelerates the coagulation time. The adrenolytic drug, piperidylmethyl benzodioxane, when added *in vitro* inhibits both the *in vitro* and *in vivo* clot-accelerating effect of epinephrine and nor-epinephrine. Piperidylmethyl benzodioxane does not prolong blood coagulation when added to whole blood *in vitro*. This fact together with its effect on the coagulation of blood to which epinephrine or nor-epinephrine has been added *in vitro* or *in vivo* indicates that its action is directly against these sympathomimetic compounds. Furthermore it suggests that the accelerating effect of these sympathomimetic compounds on whole blood coagulation is one similar to a catalyst and not due to a change in the reacting compounds.

Relation of quick stretch and twitch response in skeletal muscle SHEPPARD M WALKER *Dept of Physiology, Univ of Louisville School of Medicine, Louisville, Ky*

The *in situ* triceps surae of male rats weighing 150 to 200 gm and the isolated sartorius muscle of the frog were arranged for optical recording with an isometric lever. The frog muscle was stimulated directly and the rat muscle was stimulated through the cut sciatic nerve. The muscle was stretched by displacement of the fixed end with a strong spring. Observations were made on muscle at initial lengths varying from 20% below to 20% above the length required for a maximal twitch. At lengths equal or above that required for a maximal twitch, quick stretch decreased twitch tension. At shorter lengths adequate quick stretch increased twitch tension up to, but never above, maximal twitch tension. Twitch tension was determined by subtracting the tension induced by quick stretch. Twitch contraction at the shorter lengths markedly increased the resistance of the muscle to quick stretch. Twitch contraction at lengths equal or above that required for a maximal twitch usually decreased the resistance of the muscle to quick stretch. Resistance is directly proportional to the amount of deflection of the isometric lever by the stretch. It was concluded that 1) quick stretch modifies twitch tension in a manner predictable from the length-tension diagram, and 2) the effect of twitch contraction on the resistance of the muscle to quick stretch is dependent upon the initial length of the resting muscle.

Effects of electrical stimulation of temporal lobe in the rhesus monkey P D WALL AND G D DAVIS (introduced by J F FULTON) *Lab of Physiology, Yale Univ School of Medicine, New Haven, Conn*

Stimulation of an area of cortex extending from the tip of the temporal lobe to the interaural plane on the inferior and medial surfaces of the temporal lobe produces marked changes of blood pressure and respiration. Similar changes could be evoked from the amygdala but not from ammon's horn. The responsive area of the temporal cortex differs from that on the orbital surface in the direction and intensity of blood pressure response and in the participation of the hypothalamus in the mediation of the response. Some evidence indicated that the hypothalamus was not involved in the pathway from the temporal cortex which passed directly to the lateral part of the midbrain. Areas controlling blood pressure did not completely coincide with those controlling respiration. Stimulation of exactly the same area may produce either hyperpnea or apnea and a hyperpneic response may be converted to

an apneic by administration of bulbo-capnine. Motor movements have been reported from stimulation of the temporal lobe but most of these appear to be due to direct stimulation of the 5th nerve.

Volume and enzyme response of the transplanted pancreas to foodstuffs in the intestine C C WANG* AND M I GROSSMAN *Dept of Clinical Science, Univ of Illinois College of Medicine, Chicago*

In 3 chronic dogs with a portion of the pancreas transplanted subcutaneously, a basal level of secretion was maintained by continuous intravenous injection of purified secretin. When the volume rate and enzyme output (amylase) had become constant, the test substance was introduced through a metal cannula in the duodenum and the effect on secretory rate and amylase output noted. The results may be summarized as follows (in this list the first number indicates the number of tests performed, the second, the average percentage increase in volume rate over the control period, and the third, the average percentage increase in amylase output over the control period): 50 cc distilled water, 5, +20, +34, 50 cc saline, 6, +5, +16, 20 cc 0.5% HCl, 9, +168, +162, 20 cc 5% Bacto Protone, 7, +82, +313, 20 cc 5% amino acids solution, 4, +52, +340, 10 cc corn oil, 2, +10, +71, 20 cc 5% sodium oleate, 3, +36, +50, 20 cc 5% dextrose, 2, +0, +16, 20 cc 10% maltose, 3, +0, +0. Since nervous connections between the intestine and the pancreas are absent in these dogs, increases in volume rate may be attributed to secretin release and increases in enzyme output to pancreozymin release. On this basis, HCl is the most potent stimulator of secretin release and peptone and amino acids are the most potent for pancreozymin release, although both hormones are released to some extent in both instances. These experiments constitute crucial physiologic proof for the existence of pancreozymin.

Further evidence for thyroid regulation of gastric function R N WATMAN* AND E S NASSET *Dept of Physiology and Vital Economics, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*

It was reported earlier that thyroidectomy reduces the survival time of guinea pigs with histamine-induced peptic ulcer. Death due to perforated peptic ulcer and peritonitis occurred in the normal animal in 135 ± 20 hours and in the thyroidectomized animal in 56 ± 8 hours. Administration of thiouracil in doses which lowered the oxygen consumption to the level of the thyroidectomized animals did not alter survival time (125 ± 29 hours). Administration of thiouracil to thyroidectomized animals failed to improve

their survival time. The results of thiouracil treatment suggest that thyroxin may not be concerned in the thyroid effect on gastric function. Auto-transplantation of the thyroid failed to affect survival time, indicating that anatomical integrity is not a significant factor. Crystalline thyroxine was administered to thyroidectomized animals in the amount adequate to restore the oxygen consumption to normal ($\pm 10\%$). This did not improve the survival time as compared with the untreated thyroidectomized group. Administration of whole desiccated thyroid substance, however, to thyroidectomized animals in adequate amount restores to normal both the oxygen consumption and ulcer survival time. These studies suggest that 1) The thyroid has an effect on gastric function which may be independent of the action of thyroxin. 2) In addition to thyroxin, the thyroid may produce an active principle which regulates gastric function. 3) These effects are not due to damage to the parathyroids, vagi or other structures. This is indicated by the auto-transplantation studies and the fact that adequate substitution by thyroid substance alone was demonstrated.

Interaction of fibrinogen and thrombin DAVID F. WAUGH AND BETTY J. LIVINGSTONE * *Dept of Biology, Massachusetts Inst of Technology, Cambridge*

Fibrinogen and thrombin (Armour) interaction has been examined over the ranges 0.036 to 0.35 mg clottable N/ml at 0.045 U thrombin/ml and 0.009 to 0.454 N I H U/ml thrombin at 0.18 mg C N/ml. Aliquots of fibrinogen and thrombin were mixed in paraffined tubes. At appropriate times the reaction was stopped by retracting the clot and adding formaldehyde to 1.8% final concentration (7 sec). After centrifugation, the supernatants were analyzed by ultraviolet absorption ($\lambda = 280 \text{ m}\mu$) for their contents of non-clottable protein and residual fibrinogen. When plotted as pseudo first-order reactions all have an initial non-linear portion extending to approximately $\ln \theta^{-1}$ equals 0.4 ($\theta =$ fraction residual fibrinogen). Beyond this point linearity (vs time) is observed. An extrapolation of the linear portion passes through the origin. The initial non-linear portion is considered to represent the accumulation of activated fibrinogen, the linkage of activated fibrinogen to form a retractable clot and the formation of a sufficient number of fibrin fibrils to keep the concentration of activated fibrinogen at a low and negligible value. The linear portions of all of the reactions so far examined are described by the equation
$$-d\phi/dt = \frac{10.21 Th_0}{1 + 22.8 \phi_0} \phi$$
 where Th_0 and ϕ_0 are the initial concentrations of thrombin and fibrinogen, respectively. The interpretations of this equation will be discussed.

The interpretations of this equation will be discussed.

Measurement of hepatic circulation by clearance of radioactive sodium in man RICHARD L. WECHSLER,* LOUIS SOKOLOFF* AND SEYMOUR S. KETY *Dept of Physiology and Pharmacology, Graduate School of Medicine, Univ of Pennsylvania, and Diabetic Coma Project, Philadelphia General Hospital, Philadelphia, Penna*

The clearance of radioactive sodium from the liver has been measured by a method previously described for the gastrocnemius muscle (KETTY, S. S. *Am Heart J* 38: 321, 1949). In this study, $5 \mu\text{C}$ of Na^{24}Cl in 1 cc of isotonic saline was injected into the liver through a 22 gauge, 4-inch needle with the patient in the supine position. The injection site, 2 interspaces below the appearance of liver dullness in the right midaxillary line, was sterilized and then anaesthetized with procaine hydrochloride. The patient was instructed to exhale completely and refrain from inhaling during injection of the needle. The Na^{24}Cl solution was injected as the needle was withdrawn. Slight discomfort was the only complaint upon injection. A Geiger-Müller counter was placed over the liver at the level of injection. Counts were recorded at half-minute intervals until a final plateau was reached. Counts per half minute less the final background were plotted semilogarithmically against time and a straight line resulted. The slope of this line yields the value for k or the clearance constant. This constant, representing the ability of the hepatic circulation to remove or supply nutritional substances, is a measure of the effective circulation through the liver tissue. Hospitalized patients, without circulatory or hepatic disorders (normal liver function tests) were chosen at random. Values for the hepatic clearance constants in this group ranged from 0.344 to 0.483 with a mean of 0.402. This mean is 8 times the mean clearance constant of the resting gastrocnemius muscle ($k = 0.050$).

Effect of auricular fibrillation on cardiac output, coronary flow and arterial blood pressure RENÉ WÉGRIA, CHARLES W. FRANK,* GEORGE A. MISRAHY,* ROBERT S. SIOUSSAT,* LEONARD SOMMER* AND GEORGE H. MCCORMACK, JR * *Dept of Medicine, College of Physicians and Surgeons, Columbia Univ, and the Presbyterian Hospital, New York City*

The effect of auricular fibrillation on the cardiac output, coronary blood flow, and mean arterial blood pressure was studied in dogs anesthetized with pentobarbital. The cardiac output of the left ventricle and the blood flow in the left descending anterior coronary artery were recorded continuously with two rotameters. The mean

arterial blood pressure was recorded continuously with an optical manometer. Thirty-three bouts of electrically induced auricular fibrillation lasting from one-half to five minutes were studied in 9 dogs. At the onset of fibrillation, there is an abrupt fall in cardiac output, blood pressure and coronary flow. After a few seconds, there is some rise in all three toward control. At the termination of fibrillation, there is a sudden increase in all three to levels greater than control. Following the shorter bouts of fibrillation, cardiac output, coronary flow and arterial blood pressure return to control simultaneously. In a few of the shorter bouts and in most of the longer ones, the coronary flow is still increased above control level when both cardiac output and blood pressure have returned to control values.

Blood changes in guinea pigs during deficiency of anti-stiffness factor VIRGINIA WEIMAR* AND ROSALIND WULZEN *Dept of Zoology, Oregon State College, Corvallis*

Guinea pigs raised on a diet adequate in minerals and in the known vitamins, with the exception of the anti-stiffness factor, develop a deficiency disease characterized by muscular stiffness in the early stages and later by heavy calcium deposits in many organs (WULZEN AND BAHR *Physiol Zool* 9: 508). During the deficiency there was produced a hypocythemic, normochromic and normocytic or macrocytic anemia. The number of young red cells in the circulating blood was decreased. Erythrocytic sedimentation was more rapid, and, in the early stages of the deficiency, the increase in sedimentation rate paralleled the development of wrist stiffness. Deficient guinea pigs showed a leucocytosis of 16,700/cu mm as compared with 7,700 for non-deficient guinea pigs. Male guinea pigs fed the deficient diet for 10-14 weeks had an increased percentage of neutrophils and a decreased percentage of lymphocytes and Kurloff cells. Males deficient for 24-110 weeks had abnormally high percentages of neutrophils and eosinophils, a decreased percentage of lymphocytes and the complete disappearance of the Kurloff cells. Stiff male and female guinea pigs fed the deficient diet 24-110 weeks showed a persistent eosinophilia, the degree of eosinophilia increasing with the stiffness. In only 2 out of 85 cases was severe stiffness not accompanied by eosinophilia, and one of these had a 6% basophilia.

Studies on heparin release in anaphylactic shock dogs RICHARD P. WHITE, PARKE H. WOODARD (introduced by O. O. STOLAND) *Dept of Physiology, Univ of Kansas, Lawrence*

Since the theory that heparin appears in the circulation of anaphylactic dogs has received support, it was thought worth-while to study heparin concentration in the blood and thoracic

duct lymph in both actively and passively sensitized dogs using the protamine titration method. Ten dogs were used as donors. They were sensitized to horse serum and at times varying from 4 to 32 days afterward bled enough blood to passively sensitize normal dogs. These were anesthetized, and blood pressure recorded. Both blood and thoracic duct lymph samples were obtained. Records were obtained before and after the injection of shock doses of horse serum. Some dogs were donors more than once. Seventeen attempts at passive immunization were made. As indicated by the characteristic fall in blood pressure, 7 were unsuccessful, 7 were successful, 2 of which gave anaphylactoid responses with recovery on the transfusion of blood and then responded by a drop in pressure to the injection of horse serum, and 3 gave anaphylactoid responses only. On the injection of horse serum only one showed any immediate change in blood coagulation time or indication of heparin in the blood. In 4, lymph coagulation was markedly slowed and more heparin appeared than in blood. Perhaps the lymph serves as an entrance of heparin into the blood. Seven donor dogs were similarly studied. The results are essentially the same. Lengthening of coagulation time occurred first in the lymph, often not appearing in the blood at all and heparin concentrations were always found higher in lymph.

Inhibition of catabolic effect of ACTH on nitrogen metabolism by a high potassium diet JOHN E. WHITNEY* AND LESLIE L. BENNETT *Division of Physiology, Inst of Experimental Biology, and the Division of Medicine, Univ of California, Berkeley and San Francisco*

Four groups of 5 'plateaued' female rats of the Long-Evans strain were maintained on a constant daily food intake. In one group 600 mg of KCl were added daily to the diet of each animal, and in another group 720 mg of KCl were added daily. The remaining 2 groups served as the normal controls. Individual urine specimens were collected daily and were analyzed for total nitrogen. The period of ACTH administration was preceded and followed by control periods of from 9-18 days. The addition of the above amounts of KCl to the diet did not alter the nitrogen balance. When ACTH at a dose of from 6-9 mg/day was given to the rats receiving the 600 mg/day of KCl their average daily urinary nitrogen excretion rose from 337 to 354 mg/rat/day while that of their controls rose from 337 to 381 mg/rat/day. When a larger dose of a less active ACTH preparation was given to the animals receiving 720 mg KCl/day the average daily nitrogen excretion changed from 388 to 381 mg, while that of their controls rose from 377 to 423 mg/rat/day. In

neither experiment prior to the administration of ACTH was the urinary nitrogen of the control animals significantly different from that of the animals fed KCl. In each experiment the urinary nitrogen during ACTH administration was significantly higher for the control rats than for the rats fed KCl.

Glucose formation in eviscerated rabbit ARNE N WICK,* DOUGLAS R. DRURY AND EATON M. MACKAY *Scripps Metabolic Clinic, La Jolla, Calif*

Recent work has shown that after removal of the liver the kidneys form sugar. It is important to know whether this sugar is made from non-carbohydrate sources or whether it is formed by rebuilding fragments of broken down glucose molecules. We have investigated this question by injecting a quantity of C^{14} labeled glucose into an eviscerated non-nephrectomized rabbit. After allowing 30 minutes for mixing, a sample of blood is taken. The concentration of glucose in the sample is determined using fermentation for identification. The radioactivity of the CO_2 produced by the fermentation is also determined. No further glucose is administered and the blood sugar steadily declines. After 3 or 4 hours and when the blood sugar is quite low another blood sample is taken and the determination repeated. If new glucose has been formed from any source other than broken down glucose molecules, this would be indicated by an increase in the ratio of blood glucose to the radioactivity of the CO_2 liberated by fermentation. We have found this to be the case although calculations indicate that a significant part of the glucose formed by the kidneys comes from former glucose fragments. The other sources of glucose will be discussed.

Effect of increased temperatures on certain constituents in the blood of the turtle CHARLES G. WILBER AND JOSEPH F. SCHANNO * *Biological Labs, St. Louis Univ., and Dept. of Biology, Stonehill College, St. Louis, Mo*

Samples of blood were removed from 10 turtles (which had been kept at 22°C for 24 hours) of the species *Chrysemys picta* and analyzed for glucose, urea and uric acid to obtain 'normal' values. The mean values for these substances in milligrams per 100 cc of blood are as follows: glucose, 65.1, urea, 27.0, uric acid, 4.8. Groups of turtles (10 in each group) were exposed to temperatures of 32°C and 38°C respectively. After 24 hours' exposure, blood was removed directly from the ventricles and analyzed for the constituents mentioned above. It was found that the glucose in the blood of turtles exposed to these increased temperatures shows a definite increase above the so-called normal values as given previously. Similarly, an increase of urea above the

so called normal was found. On the other hand, no increase was found in the amount of uric acid in the blood of turtles exposed to 32°C and 38°C respectively. It might be concluded that the increase in glucose and urea with increase in temperature indicates that the liver is stimulated to increased activity by these elevated temperatures. On the other hand, the constancy of the uric acid levels in the turtle under conditions of temperature stress indicates that purine metabolism is not markedly changed under the conditions of the present experiments. These results are in accord with other work (*Anat. Rec.* 105:97, 1949) on blood lipids of the turtle. Increased temperatures bring about a significant increase in BMR of the turtle. Whether or not the reported changes persist for a long time is not clear. Work is now in progress in an attempt to ascertain whether turtles exposed to elevated temperatures for periods up to one month show a consistent change in blood constituents.

Studies on blood pressure in dogs using an auscultatory method C. M. WILHELMJ AND E. B. WALDMANN * *Dept. of Physiology, Creighton Univ. School of Medicine, Omaha, Nebr.*

We sought a method whereby daily or multiple daily readings could be made on unanesthetized dogs for months or years. Since the animals were to be subjected to various types of stress it was felt that arterial puncture would be infeasible. We have been using the method of F. M. Allen with the difference that the dogs are recumbent. To date 11 dogs have been intensively studied. Careful training is essential. The training is in two stages: 1) the *objective* stage during which the animal learns to lie quietly on the table for the prescribed period of time, 2) the *subjective* period during which the animal loses fear and apprehension and becomes accustomed to the procedures. The time necessary for complete training varies from a few weeks to several months. In untrained animals great variations in pressure and sounds occur. In properly trained animals two types of curves appear: 1) low pressures with small daily fluctuations, 2) high pressures with large daily fluctuations. Readings must be taken under basal conditions. Shivering, panting, movement of muscle tension must be avoided. The presence of strangers, loud noises, unusual manipulations or changes in routine often cause elevations in blood pressure. The training and conditions necessary to secure basal blood pressure are similar to those necessary to obtain true basal metabolism. The same person should take the readings on each dog. Tests with mecholyl and pitressin have shown the expected changes. Two different observers have been found to obtain readings in satisfactory agreement.

Adrenalectomy on frog skin potentials MARTIN W WILLIAMS* AND CLIFFORD A ANGERER
Dept of Physiology, Ohio State Univ, Columbus

This laboratory is interested in certain physico-chemical properties of cells and tissues as influenced by changes in the concentration of certain steroid hormones. Initial work on frogs show that isolated skin increases its permeability to certain radioactive isotopes and changes certain of its bioelectric properties following adrenalectomy. The P D across the skin was determined by a null-point potentiometer in conjunction with the following cell, calomel/Ringer-Agar/Ringer's solution/skin/Ringer's solution/Ringer-Agar/calomel. Male *Rana pipiens* were divided into 3 groups: Adrenalectomized, renal damaged (sham-operated), and unoperated frogs. The latter 2 groups served as controls. All ventral skins were removed and kept in Ringer's solution buffered with phosphate solution at pH 7.4 from $\frac{1}{2}$ to 1 hour prior to potentiometric study. Zero time was measured from the close of this immersion period. At the end of one hour (i.e., $1\frac{1}{2}$ –2 hours after removal of skin) of recording the potentials at 10-minute intervals there was a decrease in the mean value of 58% for skins of adrenalectomized frogs compared with controls. No significant change was observed for mean values of skins from renal damaged and normal frogs. Further studies are underway.

Reactions of diet-induced fatty livers of rats to an acid diazo dye W LANE WILLIAMS AND DAVID W HOLANDER * *Dept of Anatomy, Univ of Minnesota, Minneapolis*

Large amounts of parenterally injected acid diazo dyes are not immediately hepatotoxic, are not excreted by, and do not stain the cytoplasm of normal hepatic parenchymal cells of rats and mice. Centrilobular cells of livers damaged by CCl_4 are immediately stained (cytoplasm) by such dyes and remain stained until they undergo lysis (*Anat Rec* 101:133, 1948). Fatty livers were produced by a low protein (4%)-high fat diet during the 5th–10th weeks of life. Terminally, subcutaneous or intraperitoneal injections of 1 to 2 cc of 0.5% aqueous trypan blue were given for 3–7 days. Macrophages were free of fat but contained large amounts of dye. The large, fat-filled, parenchymal cells were not stained by trypan blue. Such atypical cells were not permeable to dye and no significant amount of fat was deposited in active or potential macrophages. A few small areas of inflammation were observed in which liver cells contained dye and fat. The local tissue reactions indicated that an additional injurious process was active in such sites. These rats weighed 40–60 gm initially and the diet permitted no increase in body weight. Terminally

parenchymal cells contained large amounts of fat. Slightly older rats (100–120 gm) fed the same diet showed no increase in weight but liver cells were not distorted and liposis was limited to small cytoplasmic droplets. Such cells were also free of dye while adjacent macrophages were filled with granules of trypan blue.

Ventricular fibrillation in delayed treatment of TEPP poisoning J H WILLS, B P McNAMARA* AND E A FINE * *Pharmacology Section, Med Division, Army Chemical Center, Md*

In the dog poisoned by intravenous injection of TEPP, delay in administration of atropine for longer than 4–5 minutes may result in rapid death of the animal from ventricular fibrillation following injection of the atropine. If respiratory paralysis has occurred before atropine administration, ventricular fibrillation follows that therapy in every case. This action is not a specific property of atropine, resulting also from the use of the diethyl aminoethyl ester of 1-phenyl cyclopentyl monocarboxylic acid (Panparnit). In the dog with paralyzed respiration, administration of artificial ventilation before atropine therapy allows recovery of the animal. It is believed, therefore, that the fibrillation following delayed treatment with atropine of TEPP poisoning depends upon a sudden increase in the work demanded of a severely anoxic heart.

Activity of inhibitors of acetylcholine esterase as function of pH IRWIN B WILSON AND FELIX BERGMANN (introduced by DAVID NACHMAN-SOHN) *Dept of Neurology, Columbia Univ, College of Physicians and Surgeons, New York City*. The inhibition of acetylcholine esterase by various inhibitors has been investigated as function of pH. Hereby information may be obtained as to the mechanism of interaction between the enzyme protein and the inhibitors and as to the nature of the structure hydrolyzing acetylcholine.

The inhibition by eserine decreases linearly with increasing pH, prostigmine action is virtually unaffected. The results show that the cationic form is the stronger inhibitor. They suggest a negatively charged structure as part of the active surface. A completely different type of pH-dependence is found with TEPP. Since this electrically neutral compound remains unchanged within the pH range of enzyme activity, all variations of inhibition must be ascribed to changes of the active structure of the protein. TEPP inhibition as function of pH shows a maximum close to 7, the shape of the curve being similar to that of the pH activity curve of the enzyme itself. Assuming that TEPP does not interact with the anionic but with the other part of the active center, the parallelism suggests that the pH-activity curve of the enzyme reflects the changes of this second

part The pH effects can best be interpreted as the dissociation of 2 acid groups These results will be discussed in the light of observations on salt effects

Time of consciousness at high altitudes J W WILSON AND ELIZABETH COMFORT * *Aero Med Lab, Air Materiel Command, Wright-Patterson Air Force Base, Dayton, Ohio*

It has been observed that time of consciousness following oxygen mask removal at a given altitude is considerably longer than the time available following rapid decompression to the same altitude In view of the importance of the observation in connection with the establishment of safety procedures in pressurized aircraft, a comparison of these two sets of conditions has been made in 6 resting individuals for an altitude range of 25,000-40,000 feet These experiments have demonstrated that the time reserve is 27-49% longer in the mask removal than in the rapid decompression series With individuals working mildly (1800 ft lb/min, bicycle ergometer) the time of consciousness following rapid decompression was reduced by 25-50% below that of resting individuals By use of our data on air-breathing subjects at rest and of data obtained by Hornberger on resting individuals breathing oxygen (*U S Air Force, AMC, Engineering Division Memorandum Report TSEAA-660-83-E, 5 February 1946*), a graphic comparison has been made which gives some indication of the importance of the 'nitrogen-dilution effect' (*Proc Soc Exper Biol & Med* 70 185, 1949) in determining the duration of consciousness of air-breathing individuals after explosive decompression to high altitudes The validity of applying the widely used term 'time of useful consciousness' to both of the two practically important situations in aviation in which consciousness may be lost as a result of hypoxic hypoxia, is questioned, since the victim may be entirely unaware of the threatening danger

An analysis of cerebral control of reflex pupillary dilatation in the cat and monkey WILLIAM CROSBIE WILSON (introduced by A G MULDER) *Dept of Physiology, Stritch School of Medicine, Loyola Univ, Chicago, Ill*

It was found that cerebral reflex pupillary dilatation follows adequate cortical and subcortical excitation of the 1) gyri proeus, genualis, and subcallosus in cats, and 2) the cruciate gyrus (area 8) in the Rhesus monkey Partial denervation of the pupil, by sympathetic chain section in some experiments, and in others by ciliary ganglionectomy in cats and monkeys demonstrated Frontal lobe reflex pupillary mydriasis in cats is due to active inhibition of parasympathetic activity, in monkeys to predominately sympathetic activity Response to the light reflex and a study

of ciliary ganglion action potentials before, during and after frontal lobe stimulation substantiates the resulting mydriasis in cats to be due to inhibition of para-sympathetic tone In addition evidence indicates that centrifugal frontal lobe fibers controlling the light reflex by active inhibition of parasympathetic activity pass through the hypothalamus to the Edinger-Westphal nucleus

Changes in endocrine organs induced by bacterial pyrogens W F WINDLE, H H WILCOX,* RUTH RHINES,* AND C CLEMENTE * *Dept of Anatomy, Univ of Pennsylvania School of Medicine, Philadelphia*

We studied histologically with controls most organs of 2 series of female rabbits, one receiving Baxter Pyromen, PsP, (of pseudomonas origin) in 100-200,000 γ dosages over periods of 19-303 days, and the other receiving Baxter Pyromen, PVP (of proteus vulgaris origin) in dosages of 500-20,000 γ /kg thrice weekly for 3-6 weeks (lb 50, about 75,000 γ) Neither series showed vascular, renal or intestinal lesions resembling exhaustion stages of the general adaptation syndrome The PsP-treated rabbits exhibited hyperplasia and hyperactivity of lymphatic and reticuloendothelial tissues Administration of PVP induced only slight changes in such tissues Both preparations produced blood picture changes like those after stress or administration of ACTH Certain changes suggestive of involution after an earlier phase of marked growth stimulation were found in the adrenal cortex of both series Other controlled series of rabbits and rats were given PVP, 1 γ /kg daily or 5 γ /kg thrice weekly for 12 hours-122 days Most endocrine organs underwent changes suggestive of increased cytoplasmic activity The anterior lobe basophils and cells of pars intermedia of the hypophysis showed increased cytoplasmic vacuolization within 12 hours Similar changes appeared in the adrenal cortex Stroma cells of the virgin ovary became swollen Administration of PVP for longer periods led to widening of the adrenal zona reticularis without total cortical hypertrophy Prolonged high doses of PVP caused reduction in the anterior lobe basophil population and involutional changes in the zona reticularis

Influence of cortisone and related steroids upon spreading effect of hyaluronidase CHARLES A WINTER AND LARS FLATAKER * *Merck Inst for Therapeutic Research, Rahway, N J*

The spread of the dye T-1824, after intradermal injection both with and without added hyaluronidase, has been studied in mice and rats In mice, as Opsahl has shown, adrenalectomy increases the area of the spread, but in rats maintained in good condition with 1% NaCl to drink, a difference between the spread of dye in normal and adrena-

lectomized animals can be shown only if saline is withdrawn and the animals fasted overnight. In both species, and in both adrenalectomized and intact animals, cortisone acetate or adrenal cortex extract (ACE), if administered intramuscularly prior to the test, strongly inhibits the spreading action of hyaluronidase, and moderately inhibits the spread of the dye in saline. ACE is also effective in inhibiting the spread if injected locally (intradermally, mixed in the syringe with the dye) in amounts as small as 0.025 ml, but cortisone in quantities up to 0.25 mg is completely ineffective when administered in this way. Steroids which inhibit the spreading factor when injected intramuscularly 0.5 mg daily for 3 days prior to test include the following: cortisone acetate, testosterone propionate, Δ 4-androstenedione-3,17, and Δ 4-3,20-diketo 17 hydroxy-21-acetoxypregnene. Steroids similarly administered which do not inhibit the spread include desoxycorticosterone acetate and Δ 4-androstenedione-3,11,17. No clear relationship is so far apparent between chemical structure and activity in inhibiting the spreading factor. Anesthesia has been found to influence the results, since Evipal exerts a marked, though temporary, inhibition of the spreading factor, while ether is without effect.

Relation of constituents of gastric juice to occurrence of mucosal erosion and bleeding STEWART WOLF AND GEORGE B. JERZY GLASS * *New York Hospital, and the Dept of Medicine, Cornell Univ. Med. College, New York City*

Special interest attaches to the noxious effects of acid and pepsin on the one hand, and the protective action of the constituents of gastric mucin on the other, in determining the occurrence of injury to the gastroduodenal mucous membrane. Since the recent introduction of a method for fractionating gastric mucin which allows separation of the glandular product (mucoprotein) from that secreted by the lining columnar epithelium (mucoproteose), it has become possible to correlate quantitatively mucus secretion with acid and pepsin. In the current study, performed on the fistulous subject, Tom, a day-to-day photographic record in color of the gastric mucosa was correlated with changes in acid, pepsin, mucoprotein and mucoproteose secretion. Special attention was directed to the fragility of the membrane and to the presence of hemorrhagic spots and erosions. At the same time throughout this period a careful record of life situation, attitude and emotion was kept. After central vagus stimulation by intravenously administered insulin, or during sustained personal conflict with anxiety and resentment, HCl, pepsin and mucoprotein concentration were increased, while mucoproteose concentration was

low. Under these circumstances the membrane was red and engorged and there was the greatest evidence of susceptibility of the membrane to injury. Under resting fasting circumstances there was no constant relationship among the various secretory constituents, but high acid with low mucoproteose concentration seemed to be the circumstance most favorable to the occurrence of hemorrhage and erosion in the membrane.

Effect of estrogen on iodine turnover in thyroids of rats and mice L. F. WOLTERINK, C. C. LEE, K. OLSEN AND M. MURRAY (introduced by J. MEITES) *Dept of Physiology and Pharmacology, Michigan State College, East Lansing*

Although estrogens have very little effect on the early uptake of iodine in the rat (K. E. PASHKIS, A. CANTAROW AND W. C. PEACOCK, *Proc Soc Exper Biol & Med*, 68:485, 1948), they have been shown to retard the output of iodine from the thyroid of the chick if administered daily for a 2-week period (EPSTEIN AND WOLTERINK, *Poultry Sci* 28:763, 1949). In the present experiments, an attempt was made to demonstrate the effect of various dosages of the dimethyl ether of stilbestrol on the turnover rate of iodine in the thyroids of rats and mice. Turnover rates were computed from the average counts of I^{131} made on whole dry thyroids removed at autopsy 18 and 68 hours after injection of radioiodine. Estrogen dose rates of 1 μ gm/animal/day intraperitoneally for 3 days increased the output of I^* from the thyroid both in rats and mice. Ten μ gm and 100 μ gm doses for the same period and massive single doses usually depressed I turnover. The observation of Meites and Chandraseker (J. MEITES AND B. CHANDRASEKER, *Endocrinology* 44:368, 1949) that the mouse has a lower thyroid activity per unit body weight than the rat was confirmed.

Relationship between thyroid activity as assayed by the thiouracil-thyroxine method and by the thyroid turnover of radioiodine in pair-fed rats L. F. WOLTERINK AND C. C. LEE (introduced by W. D. COLLINGS) *Dept of Physiology and Pharmacology, Michigan State College, East Lansing*

By the method of Dempsey and Astwood (E. W. DEMPSEY AND E. B. ASTWOOD, *Endocrinology* 32:509, 1943), the thyroid secretion rate in a group of pair-fed 70-gm male Rockland rats was determined to be 5.36 D,L-thyroxine μ gm D,L-thyroxine/100-gm body weight/day. The turnover rate of I in the thyroids of the same group, computed from I^{131} counts 40 and 80 hours after I^* injection, was 25.6%/day. If an iodine concentration in the thyroid of 70 mg % is assumed (D. A. MCGINTY, *Ann N Y Acad Sci* 50:403, 1949), and if the thyroid is forming only L-thyroxine instead of the racemic mixture, the corrected

thyroxine secretion rate, computed from this turnover figure for these rats, is 5.16 μg D,L-thyroxine/100 gm body weight/day. The difference of 4% between the 2 figures is not statistically significant.

Objective method for measurement of systemic arterial pressure in intact human ear. EARL H. WOOD, EDWARD H. MORGAN* AND GABRIEL G. NAHAS* *Section on Physiology, Mayo Fdn., Univ. of Minnesota, Rochester*

Simultaneous recordings of intraradial arterial pressure at eye level and of ear opacity pulse in 20 normal subjects during exposure to positive acceleration on the human centrifuge (*Federation Proc* 5:59, 1946) demonstrated close correlation between amplitude of ear pulse and systolic pressure when arterial pressure fell below 50 mm Hg. Ear pulse uniformly disappeared and returned simultaneously with reduction of systolic pressure to zero and its recovery. Indication that blood circulating in the flushed ear was at arterial pressure led to an attempt to estimate blood pressure by measurement of the externally applied pressure required to obliterate the ear opacity pulse. A modified oximeter earpiece was used. The translucent earpiece pressure capsule was 20.5 mm in diameter. Reflected light from non-pressurized portions of the pinna was minimized by masking the photocell and ear end of the pressure capsule by 2 rings 8 mm in diameter. The photocell was connected in series to a condenser and a Moll Micro Galvanometer (sensitivity 0.006 μ amperes/mm at 4 meters). Attenuation of low frequencies caused by insertion of the condenser was 50% at 2.7 cycles/sec. Earpiece capsule pressure, ear pulse, EKG, and intraradial pressure were photographed simultaneously during determination of brachial artery pressure by auscultation in 20 normotensive and hypertensive subjects. When thickness of the ear pulse trace line was approximately 1 mm and the control ear pulse amplitude 5-10 mm, the intracapsular pressure at which the ear pulse was first discernible correlated with directly determined systolic pressure more closely than systolic pressure determined by auscultation. Correlation between the intracapsular pressure at which the ear pulse attained maximum amplitude (10-55 mm) and direct intra-arterial diastolic pressure was not significantly different from the correlation between direct and auscultatory diastolic pressures.

Antagonism of adrenocorticotrophic hormone (ACTH) and adrenal cortical extract (ACE) to desoxycorticosterone (DCA) pathological changes. DIXON M. WOODBURY,* CHARLES A. ROSENBERG* AND GEORGE SAYERS. *Depts. of Pharmacology and Physiology, Univ. of Utah and Veterans Hospital, Salt Lake City*

ACTH and ACE antagonize the following actions of DCA: 1) hypertension, 2) electroshock threshold elevation, 3) insulin hypersensitivity. Experiments were designed to test the possibility that the antagonism would also apply to pathological changes induced by DCA. Twenty-three male rats were unilaterally nephrectomized and given 0.9% sodium chloride to drink. The animals were divided into 3 groups: I, untreated; II and III, implanted with twelve 15-mg pellets of DCA; III, in addition, injected s.c. with one mg ACTH (Armour) thrice daily. Animals were autopsied 30 days after the beginning of hormone treatment. DCA induced cardiac and renal hypertrophy; ACTH did not influence action of the steroid on the heart, but appeared to have a slight inhibitory effect upon renal enlargement. DCA caused interstitial myocarditis, periarteritis nodosa (particularly in the pancreas) and focal glomerulitis in varying degrees of intensity. ACTH, given simultaneously with DCA, reduced the incidence and degree of severity of the lesions. In another experiment 16 male rats were unilaterally nephrectomized, given 0.9% sodium chloride to drink, implanted with twelve 15-mg pellets of DCA and exposed to cold 8 hours daily. Half the animals received no additional treatment, each member of the remainder was injected with one-half cc of Upjohn's lipo-extract of adrenal cortex twice daily. The cardiac hypertrophy induced by DCA was antagonized by ACE. There was a tendency for kidney weights to be less in the animals treated with the combination DCA-ACE than in the rats given DCA alone.

Membrane resting and action potentials from excitable tissues. J. WALTER WOODBURY AND LOWELL A. WOODBURY (introduced by JAMES E. P. TOMAN). *Dept. of Physiology, Univ. of Utah College of Medicine, Salt Lake City*

The insertion of a capillary micro-electrode into single cells of a tissue (GRAHAM AND GERARD *J. Cell & Comp. Physiol.* 28:99, 1946; LING, *Federation Proc.* 7:72, 1948) not only gives functional isolation *in situ* with minimal damage to the cell but also permits quantitative, simultaneous measurements of the membrane resting and action potentials of that cell. Heretofore, overshoot of the action potential has been demonstrated in skeletal muscle by Nastuk and Hodgkin (*Federation Proc.* 8:175, 1949), and in squid giant axons by Curtis and Cole (*J. Cell & Comp. Physiol.* 19:135, 1942) and Hodgkin and Huxley (*J. Physiol.* 104:187, 1945). We have made similar measurements on other tissues, using capillaries of 0.5 micron tip diameter. Frog heart ventricle gives an average membrane potential of 60 mv and an action potential of 81 mv, indicating an overshoot of 21 mv. The form is monophasic and the dura-

tion corresponds to the extrinsic QT interval Preliminary results from frog sciatic nerve trunks give fiber membrane potentials as high as 100 mv, but usually 50 to 80 mv Simultaneous recordings of membrane resting and action potentials show overshoot of the spike The form of the membrane action potential is essentially that reported by Tasaki and Mizuguchi (*J Neurophysiol* 11 295, 1948) and Schoepfle and Erlanger (*Am J Physiol* 134 696, 1941) for unimpaled single frog sciatic fibers Studies on other excitable tissues are in progress

Pattern of localization in the precentral motor cortex of *Macaca mulatta* C N WOOLSEY AND P H SETTLAGE * *Depts of Physiology and Anatomy, Univ of Wisconsin Med School, Madison*

Somatic sensory and motor areas of the rat's cerebral cortex are so organized as to form somewhat distorted body images in which the various parts are related to one another much as in the actual animal The sensory and the motor patterns are mirror images, touching one another at snout and limb apices along a line which corresponds to the central sulcus of primates (*Federation Proc* 7 137, 1948, 8 144, 1949) We have reexamined the localization pattern in the precentral gyrus of the monkey and have been surprised to find that the motor pattern of this animal also hangs together as it does in the rat and that the accepted separation of face from trunk is not a fact In essence, fingers, toes and lower face are represented within and adjacent to the central sulcus The axes of arm and leg run rostrocaudally so that proximal parts of limbs are better represented rostrally, as are also upper face, eyelids and pinna Binding together face, arm and leg representations is an area for axial musculature, which forms the rostral border of the pattern This border corresponds approximately to the rostral limit of 4S, or the boundary between Vogt's 6 α and 6 β , as judged from gross brain maps Abdominal musculature is represented between arm and leg nearer the central sulcus The results raise the question whether the usual separation of the precentral region into physiologically distinct motor and premotor fields is justifiable

Electromyographic patterns in reinnervated muscles MELVIN D YAHR, ERNST HERZ AND JOSEPH MOLDAVER (introduced by PAUL F A HOEFER) *Dept of Neurology, College of Physicians and Surgeons, Columbia Univ, and Neurological Inst, Presbyterian Hospital, New York City*

Electromyographic studies were carried out in a group of patients having complete peripheral nerve injuries with subsequent suture, 3 to 5 years prior to examination Using a differential

high gain condenser coupled amplifier, cathode ray oscillograph, and co-axial needle electrodes, two outstanding patterns were recorded 1) spontaneous discharges below 1 mv at rest with motor unit discharges of 500 uv upon volitional contraction, 2) no spontaneous activity at rest but, upon volitional contraction, large spikes varying in amplitude from 2 to 15 mv These exhibited the characteristics of motor units, maintaining their amplitude, smooth contour and constant duration throughout a contraction, but varying in frequency with strength of contraction When compared with potentials derived from normal muscles they were 20 to 30 times larger in amplitude The first pattern was obtained from muscles giving only perceptible contraction and chronaxies 5 to 10 times normal value, the second from muscles with varying strengths of contraction but chronaxies within the normal range These findings suggest correlation between the electromyographic patterns and anatomical characteristics of re-innervated muscle The first pattern described as obtained from denervated and re-innervated fibers existing side by side during the process of reinnervation The second was obtained from reinnervated muscle in which a reconstruction of the motor units has taken place This reconstructed motor unit probably contains a larger than normal number of muscle fibers which are responsible for the large spike potentials

Regional heat loss by temperature gradient calorimetry A C YOUNG,* L D CARLSON AND H L BURNS * *Dept of Physiology and Biophysics, Univ of Washington School of Medicine, Seattle*

The data described are part of those collected in field tests at northern latitudes in an investigation of possible physiologic changes occurring during acclimatization Special suits were designed to measure heat loss These consist of an inner layer, a core layer and an outer layer of insulative material Grids of nickel wire are fastened on either side of the core layer Resistance changes in the grids indicate the temperature drop, and the heat loss may be calculated The 18 separate grids in the suit enable distinction between heat loss from the head, the back, right or left body, upper or lower arm, and upper or lower leg from the right or left side, hands, feet, and the sole of the foot Heat loss from each region and the total heat loss have been recorded Tests were carried out in the field using unacclimatized and local (acclimatized) subjects The results indicate that, under similar conditions of exposure, the heat loss from peripheral regions of acclimatized persons is maintained at a higher level than that of unacclimatized subjects Total heat loss of the 2 types of subjects will be discussed

Oxygen in carotid blood and oxygen utilization of brain in pre- and post-mature fetal rabbits

I MAUREEN YOUNG (introduced by DONALD H BARRON) *Lab of Physiology, Yale Univ School of Medicine, New Haven, Conn and Sherrington School of Physiology, St Thomas's Hospital, London, England*

To obtain post-mature fetuses the does were prepared with chorionic gonadotrophine and progesterone on the 25th day of pregnancy. An average value of 50% saturation with oxygen was found for the carotid blood in pre- and post-mature fetuses, 27-35 days old, there was considerable scatter in the figures but those obtained from the first fetus exposed in any experiment were considered the most satisfactory. Fontanelle blood from 26-31 day old fetuses was very constantly around 35% saturation with oxygen, but fell rapidly to less than 10% saturation in the post-mature period. In fetuses 25-31 days old the blood emerging from the placenta in the umbilical vein was 68-85% saturated with oxygen. The constancy of the oxygen content of the fontanelle blood demonstrates that the supply of oxygen to the brain fully meets the demands of the growing organ during the last third of prenatal life. In the post-mature period this is not the case, for though the saturation of the carotid blood with oxygen does not diminish, the coefficient of utilization by the brain increases as shown by the steep fall in the oxygen content of the fontanelle blood.

Anemia in the rabbit following treatment with relaxin

M X ZARROW AND I G ZARROW *
Dept of Biological Sciences, Purdue Univ, Lafayette, Ind

Previous studies have shown that relaxin possesses the ability to cause a water retention in the rabbit. This observation plus the fact that the rabbit not only develops an antidiuresis during the last trimester of pregnancy, but also has a high concentration of relaxin in its blood stream led to an investigation of the cellular and non-cellular elements of the blood during pregnancy and after treatment with relaxin. The anemia of pregnancy was characterized by a drop of approximately 20-30% in both the number of erythrocytes and hematocrit. A decrease was also noted for the hemoglobin and non-protein nitrogen. The reticulocytes increased while the chlorides remained unchanged. The subcutaneous

injection of castrated and normal female rabbits with 250-500 guinea pig units of relaxin 3 times daily for 3-10 days also produced changes similar to those observed during normal pregnancy. A drop occurred in hematocrit, erythrocyte count, hemoglobin and non-protein nitrogen. The reticulocytes increased markedly and the blood chlorides remained unchanged. The mean corpuscular volume tended to decrease while the mean corpuscular hemoglobin concentration was not altered.

Desoxycorticosterone hypertension in relation to hepatorenal mechanisms
BENJAMIN W ZWEIFACH AND EPHRAIM SHORR
Dept of Medicine, Cornell Univ Med College and The New York Hospital, New York City

Circulatory changes which develop in the terminal vascular bed during experimental renal hypertension in rats have been shown to be related temporally to the hepatorenal principles, VDM and VEM. A series of specific criteria were obtained by directly visualizing the circulation in the mesentery of hypertensive animals and by assaying, with the rat mesoappendix technic, the blood and tissue extracts for vasotropic activity. These include 1) hyperreactivity of terminal arterioles, metarterioles and precapillaries, 2) augmented response of these vessels to renal VEM preparations, 3) hyperplasia of mesenteric capillary bed, 4) appearance of VEM and VDM in blood, and 5) formation of VEM by kidney tissue *in vitro* under both aerobic and anaerobic conditions. Similar experiments were carried out on rats made hypertensive by administration of DCA (subcutaneously and intramuscularly) together with a high salt intake. Hypertension developed in over 90% of the rats, the pressure rising within 15-20 days, to reach 145-200 mm Hg, and in partially nephrectomized animals to about 175-200 mm Hg. None of the DCA hypertensive animals showed changes comparable to those found in renal hypertensives. No VEM appeared in the blood during the acute elevation of blood pressure, no increased reactivity of the terminal vascular bed developed, no vascular hyperplasia was seen, and no metabolic lesion developed in the kidney whereby VEM was formed aerobically, as well as anaerobically. It therefore appears that the mechanisms responsible for the development of hypertension with DCA differ from those present in the renal hypertensive syndrome.

Forty-first Annual Meeting

ATLANTIC CITY, NEW JERSEY, APRIL 17-21, 1950

(An asterisk * following an author's name indicates "by invitation")

Effects of magnesium on phosphate metabolism in vivo P H ABBISON AND EINAL AIDOUS (introduced by DEAN BURK) *Carnegie Inst of Washington, Dept of Terrestrial Magnetism, Washington, D C*

Procedures have been devised for the preparation of trace element free media by exploiting the potentialities of cation resin exchange materials. The method involves passage of all components of the medium through a resin (Dowex-50) column. All metallic cations except the alkali metals are completely removed. To date synthetic media have been principally employed, involving glucose plus inorganic salts. The purification process was checked through use of radioactive isotopes and bio-assay of the purified media. In theory and practice it is possible to obtain media absolutely freed from trace elements. The purified media have been used to study effects of magnesium on the P³² metabolism of *E coli*. In addition to an expected influence on glycolysis, the absence of magnesium has a more pronounced effect on ribonucleic acid formation decreasing the rate of synthesis by as much as a factor of ten.

Effect of incubation on the cholesterol content of rat liver homogenate W P ADAMS,* L I RICE,* M C SCHOTZ,* G F JACOBSON* AND W MARX *Dept of Biochemistry, Univ of Southern California School of Medicine, Los Angeles*

In preliminary experiments it had been observed that the amount of cholesterol extractable from liver homogenates of rats fed 1% cholesterol with the diet, decreased during incubation at 37°C (*Federation Proc* 7:171). Subsequently, however, such an effect was not consistently demonstrable, therefore, the possibility of an artifact had to be taken into consideration, in order to explain the earlier results. Upon further investigation it was observed that in some cases incubation rendered the extraction of cholesterol more difficult. As a consequence the extraction procedure was modified accordingly. In recent experiments, it was not possible to demonstrate, under the conditions so far investigated, a significant change in cholesterol concentration during incubation of rat liver homogenates.

Origin of the carbon skeleton of isoleucine EDWARD A ADELBURG* AND E L TATUM *School of Biological Sciences, Stanford Univ, California, and Dept of Bacteriology, Univ of California, Berkeley*

An isoleucine-requiring strain of *Neurospora crassa*, which accumulates in the filtrate large amounts of the isoleucine precursor α,β -dihydroxy- β -ethylbutyrate (E A ADELBURG, D M BONNER AND E L TATUM. In manuscript), was fed C¹⁴-labeled acetate. Methylene-labeled and carboxy-labeled acetate were used in separate experiments, and the isoleucine precursor produced in each case was isolated chromatographically. This material, which was found to contain high concentrations of C¹⁴, was then degraded by two different pathways: first, direct oxidation with dichromate to yield the terminal carbons as acetate, and second, cleavage with lead tetraacetate and subsequent stepwise degradation of the resulting methylethylketone and glyoxylic acid. The results of these degradations show that formation of the branched chain of isoleucine involves direct participation of acetate (probably as 'active acetate') in a coupling with a four-carbon compound, and that the latter compound is not formed directly from two-carbon fragments. Finally, the radioactive precursor obtained during these experiments has been used in investigating the utilization of this compound for isoleucine biosynthesis by other deficient micro-organisms. The significance of these findings is discussed in relation to the mechanism of biosynthesis of the carbon skeleton of isoleucine.

Studies on mechanism of acetate oxidation by bacteria SAMUEL J AJL* AND MARTIN D KAMEN *Washington Univ Med School, St Louis, Mo*

Suspensions of *E coli* adapted to oxidize acetate show heightened activity with pyruvate and C-4 dicarboxylic acids but not with α -ketoglutarate, which is attacked at the same rate by normal or adapted cells. When 2-C¹⁴-acetate is oxidized by such suspensions in the presence of unlabeled pyruvate or C-4 dicarboxylic acids, singly or in combination, considerable C¹⁴ accumulates in all

initially unlabeled substrates, except alpha-ketoglutarate. In a typical experiment with labeled acetate, unlabeled succinate, and alpha-ketoglutarate, it was found that 41% (68 micromoles) of the succinate was oxidized to acetate (or a compound in equilibrium with acetate) 25% of the alpha-ketoglutarate (30 micromoles) were decarboxylated and 25% of the acetate (44 micromoles) were metabolized. At least 7% of the acetate metabolized was assimilated while at most 52% was oxidized to CO_2 and not less than 41% condensed either directly to succinate or by way of a C-4 fragment in equilibrium with succinate. Less than 0.5% of the labeled carbon appeared in alpha-ketoglutarate. Specific activity data show that succinate carboxyl and evolved CO_2 were equilibrated. These results while not in accord with mechanisms based on a conventional tricarboxylic cycle agree quantitatively with operation of a C-4 dicarboxylic cycle condensation mechanism. Diametrically opposed data were obtained when similar experiments were performed with *M. lysodeikticus*, which attacks acetate readily. Equilibration of labeled acetate with unlabeled dicarboxylic acids was roughly 10-fold less than observed in *E. coli* and occurred to about the same extent with all substrates added, including alpha-ketoglutarate. CO_2 evolved was not in equilibrium with carboxyl carbon. Further work is planned with photosynthetic bacteria.

Phenylalanine requirements of children ANTHONY A. ALBANESE, REGINALD A. HIGGONS,* BETTY VESTAL* AND LOUKIA STEPHANSON * *Nutritional Research Lab, St. Luke's Hospital, New York City*

The available data on the amino acid requirements of man have been secured for the most part by the depletion procedure. The difference between the repletion needs so obtained and normal maintenance values increases with the duration of the depletion period which is known to involve numerous biochemical readjustments. In order to obtain amino acid requirement data which will have both practical and fundamental applications, means have been explored whereby measurements of the physiological availability of amino acids can be made under optimal dietary conditions as they prevail in life. This involves a determination of the 'saturation point' of a test amino acid which is added stepwise to the diet of subjects maintained in normal N-metabolism by natural foods fed *ad libitum*. Preliminary observations by the use of this technique show that when evaporated milk constitutes the principal source of dietary protein, the phenylalanine saturation point is reached when the diet contains 170 mg of L-phenylalanine/kg/day, for 6- to 8-month-old children. The saturation level for 3-month-old

children is reached sharply at 205 mg of L-phenylalanine. Calculations from these figures disclose that the normal phenylalanine needs of infants can be met by evaporated milk formulae which provide 4.2 gm of milk protein/kg/day for the first 3 months of life, and 3.6 gm of milk proteins for the last 6 months of the first year of life.

Nucleotide content of human blood HARRY G. ALBAUM, THEODORE CAYLE* AND ARTHUR SHAPIRO * *Dept. of Biology, Brooklyn College, Brooklyn, N. Y.*

The adenine nucleotide content of normal human blood has been studied spectrophotometrically by means of enzymes (ALBAUM, H. G. AND R. LIPSCHITZ. In press). The method utilizes perchloric acid filtrates of blood, and can be used to assay for total purine, adenylic acid, adenosine diphosphate and adenosine triphosphate on a 1 ml sample of blood. Heparinized blood remains unchanged in nucleotide content for at least 60 minutes, whereas oxalated blood, unless immediately deproteinized, changes in composition. Studies carried out on 6 normal, healthy adults, over a period of more than 3 months, indicate that the total purine level changes very little in each individual. Such bloods usually contain little or no adenylic acid or adenosine diphosphate, the greater part of the purine present is in the form of adenosine triphosphate. The nucleotide appears to be present only in the cells. Experiments are now under way on the ability of blood to synthesize ATP from added adenylic acid and other nucleotides *in vitro*.

Study of cholesterol turnover rate in using deuterium as a tracer element ROSLYN B. ALFINSLATER,* HARRY J. DEUEL, JR., MICHAEL C. SCHOTZ* AND FRANK K. SHIMODA * *Dept. of Biochemistry and Nutrition, Univ. of Southern California, Los Angeles*

Female albino rats 60 days old of the Univ. of Southern California strain were administered deuterium oxide for varying lengths of time up to 40 days. At the end of specified periods, the animals were anesthetized by injection with sodium pentobarbital (Nembutal) and sacrificed by withdrawal of blood from the heart. The following organs were extirpated: brain, lung, liver, adrenal and kidney. The cholesterol was extracted with an alcohol-ether mixture in a Soxhlet extractor. Total cholesterol was determined by a modified Schonheimer-Sperry method. The deuterium content of the isolated cholesterol was determined by combustion to water-deuterium oxide, and reduction over zinc to H_2 -deuterium. The ratio of the HD/HH was read in an Isotope-Ratio Mass Spectrometer.

Early results indicate that the greatest turnover of cholesterol in the organs investigated takes place in the adrenals. Lungs, liver and kidney follow in this order. The least amount of turnover was found in the brain. Similar experiments are in progress on rabbits.

Increased urinary excretion of choline in the phosphorus poisoned dog CARL E. ANDERSON,* C. FREEMAN LUCKEY* AND C. S. ROBINSON
Dept. of Biochemistry, Vanderbilt Univ. School of Medicine, Nashville, Tenn.

In 1935 Best and his co-workers (*J. Physiol.* 83: 275, 1934) found that choline, which protects the livers of rats from chloroform poisoning, did not prevent the fatty infiltration of the liver after phosphorus poisoning, but brought about a more rapid disappearance of fat during the recovery stage. In view of this finding, and the increase in neutral fat that occurs in the livers of phosphorus poisoned animals, it would appear reasonable to suspect an interference with the formation of transport fat. To test this hypothesis 2 healthy female dogs of average weight (8 and 12 kg.) were poisoned by the subcutaneous injection of 0.4 mg. of yellow phosphorus per kilogram body weight. The phosphorus was dissolved in peanut oil and kept in an atmosphere of nitrogen until ready for use. Urine was collected in the conventional manner. Choline was determined by both the colorimetric estimation of the Reinecke precipitate and by a manometric method to be described elsewhere. In both dogs there was found a marked increase in urinary choline as the administration of P_4 was continued. This increase was greatest just prior to death on the 8th and 10th days. Autopsy revealed typical yellow fatty livers and marked gastro-intestinal hemorrhages. When the injection of P_4 was discontinued just prior to the fatal dose and the dog allowed to recover, the excretion of choline returned to the base level. Starvation for 9 days decreased rather than increased urinary choline.

Electrometric determination of unidentified serum constituents EDNA ANDREWS* AND ADRIAN C. KUYPER
Dept. of Physiological Chemistry, Wayne Univ. College of Medicine, Detroit, Mich.

The following procedure was used for the determination of unidentified serum constituents. Protein was removed from serum by ultrafiltration, carbonate was removed by aeration of the acidified ultrafiltrate, and phosphate was removed by precipitation as calcium phosphate. The serum was ultrafiltered and the ultrafiltrate was titrated electrometrically, precision being increased by the maintenance of constant ionic strength. The identified substances present in the ultrafiltrate were determined quantitatively by accepted ana-

lytical procedures and their titration curves were calculated. The titration curve of the unidentified constituents was obtained by subtracting the curves for the identified substances from the experimentally determined curve. Eight sera from normal individuals were analyzed. The total unidentified substance titrated between pH 2.5 and 10.5 varied from 0.54 to 3.13 mEq./l. of serum. Buffer peaks were present in most of these samples at about pH 4.5, 7.0 and 9.5.

Decarboxylation of cysteic acid JAMES C. ANDREWS AND JOHN F. R. KUCK*
Dept. of Biological Chemistry and Nutrition, School of Medicine, Univ. of North Carolina, Chapel Hill

The decomposition of cysteic acid in solution under pressure yields two chief products. Alanine is produced in low yields by hydrolysis at 190°, this reaction is somewhat accelerated at higher temperatures. At 220° decarboxylation begins and as the temperature is increased the formation of taurine and carbon dioxide becomes the dominant reaction. At 240–250° fragmentation of the cysteic acid begins, producing small amounts of carbon, sulfur, hydrogen sulfide, mercaptans, sulfur dioxide and probably other products. The conversion of cysteic acid to taurine and to alanine is respectively 60–70% and less than 20%. Separation of amino acids was achieved by paper chromatography. Elution of the strips gave solutions of a single amino acid, which was determined colorimetrically with ninhydrin in the case of cysteic acid and alanine. A method for the determination of taurine in microgram quantities was developed employing the color formed by taurine, phenol and sodium hypochlorite at pH 9.5. Using an extract of rat liver as a source of cysteic acid decarboxylase (Blaschko, 1942) the disappearance of added cysteic acid from incubated mixtures was followed qualitatively with paper chromatography. The presence of appreciable amounts of preformed taurine and of substances running with cysteic acid interferes seriously with quantitative determinations.

Radioactive crystalline ribonuclease CHRISTIAN B. ANFINSEN
Biophysical Lab and Dept. of Biological Chemistry, Harvard Med. School, Boston, Mass.

Beef pancreas was sliced at the slaughterhouse as soon as possible after the death of the animal. Ten-gram portions of slices, 0.5 mm. thick, were placed in 500 ml. Erlenmeyer flasks containing 50 ml. of bicarbonate buffered medium at pH 7.4 and 38°C. (*J. Biol. Chem.*, 179: 1001, 1949). The medium included glucose at a level of 200 mg. %. Radioactivity was added as $Na_2C^{14}O_3$ through a vaccine port in the stopper of the flasks. After incubation at 38°C. for two hours, the flasks were chilled in ice and 0.5 M sulfuric acid was added to

give pH 1 Ribonuclease was isolated by a slight modification of the method of Kunitz. The final product was recrystallized once. This material was analyzed for enzyme activity, protein nitrogen and specific radioactivity. The enzyme activity-nitrogen ratios agreed with those obtained on several batches of 5 times recrystallized ribonuclease. The specific activity of the carbon dioxide liberated by ninhydrin from the washed defatted, hydrolyzed protein was about 0.1 to 0.3% that of the gas phase carbon dioxide. By using CO_2 with very high specific activity in the incubating flask it was possible to prepare ribonuclease with sufficient radioactivity to permit considerable dilution with 5 times recrystallized ribonuclease. These preparations showed constant specific radioactivity and enzyme activity upon further recrystallization. Data on phase rule criteria of purity will be presented.

Alanine as a source of acetyl groups of excreted acetyl amines in the intact animal H. S. ANKER
Dept. of Biochemistry, Univ. of Chicago, Chicago, Ill.

D- and L-alanines labeled with deuterium and carbon 14 were prepared by reduction of the corresponding phenylhydrazone of pyruvic acid with hydrogen and Adams catalyst and subsequent resolution. On feeding the labeled L-alanine together with foreign amines to rats of the Sprague-Dawley strain, identical isotope concentrations in both aliphatic and aromatic acetyl amines were found as after labeled pyruvic acid (*J. Biol. Chem.*, 176: 1339, 1948). After feeding of D-alanine the concentration of both isotopes in the acetyl group of the aliphatic amine was much higher than in that of the aromatic amine. These results account for the finding by Bloch and Rittenberg (*J. Biol. Chem.* 159: 45, 1945) that in the Sherman strain deuterio D,L-alanine gives rise to a much higher deuterium concentration in the acetyl group of phenylaminobutyric, than of p-aminobenzoic acid. It seems most likely that L-alanine is deaminated to pyruvic acid which in turn is metabolized to acetic acid, the latter acting as acetylating agent for both types of amines. For D-alanine a special mechanism to provide acetyl groups for the aliphatic amine seems to be available. It is most reasonable to assume that D-alanine reacts with a keto acid to yield an acetyl amino acid. This can then transfer its acetyl group to an aliphatic foreign amine as has been shown by Bloch and Rittenberg (*J. Biol. Chem.* 169: 467, 1947).

Procedure for the chemical estimation of free choline in plasma HAROLD D. APPLETON,* BETTY B. LEVY,* J. MURRAY STEELE* AND BERNARD B. BRODIE *Depts. of Biochemistry and Medicine, New York Univ. College of Medi-*

cine and Research Service, Goldwater Memorial Hospital, New York City

A simple method for the estimation of choline is described. It involves the precipitation of choline as an iodine complex, which is then determined in ethylene dichloride by its absorption at 365 m μ . Excess free iodine present does not interfere in the measurement. As little as 5 micrograms of choline can be accurately estimated by this procedure. Betaine, urea, creatine, creatinine, uric acid, cystine, histidine, guanidine, lysine and arginine were either not precipitated by the iodine reagent or the precipitate in ethylene dichloride did not absorb light at 365 m μ . The method has been applied to the estimation of free choline in plasma. The phospholipids are removed by acetone precipitation and the free choline estimated in the supernate. Counter-current distribution of the choline-like material measured by the procedure showed the presence of considerable material with solubility characteristics which differed from choline. This material could be separated from choline by its preferential solubility in butanol. An added step, in which the choline solution is washed with butanol prior to the formation of the iodine complex, has resulted in a specific method for the estimation of free choline in plasma. The method may also be applied to the estimation of choline in urine, in plasma phospholipids and other biological material. The free choline plasma values in normal and diseased states will be discussed.

Quantitative micro determination of thiosulfate

KAZKO ARAI, FRANK L. ALDRICH AND JOSEPH H. GAST (introduced by HOWARD B. LEWIS)
Dept. of Biochemistry, Baylor Univ. College of Medicine, Houston, Texas

Adaptation of the specific precipitation of thiosulfate as the nickel ethylene diamine salt together with the spectrophotometric measurement of the yellow iodine color at 355 m μ by the procedure of Sendroy and Alving (*J. Biol. Chem.* 142: 159-170, 1942) permits determination of isolated thiosulfate at concentrations ranging from 2.0 to 11 μg sulfur/ml. Appropriate controls must be read simultaneously to correct for dilution, oxidation and absorption by high concentrations of nickel ethylene diamine sulfate or nitrate which may be present initially or in the wash solution. Such salts show a slight absorption at this wavelength but do not reduce iodine. The conditions for reproducible precipitation require 1) alkalinity, obtained with ammonium hydroxide, 2) the presence of an equal volume of absolute ethanol, 3) at least a 300-fold excess of solid nickel ethylene diamine nitrate, 4) at least 4 hours standing at 5 to 10°C preferably overnight. Check determinations with added radioactive thiosulfate indicate

70% recoveries from urines containing concentrations of the above order of magnitude. Applications to other biological materials will also be discussed, including the problem of protein removal and losses of added thiosulfate. This procedure represents an approximately 20-fold extension of the range of thiosulfate concentration which can be determined by the usual microtitration.

Chromatographic fractionation of steroids of blood and adrenal tissue REGINALD M. ARCHIBALD AND JACQUE GENEST * *Hospital of the Rockefeller Inst for Med Research, New York City*

One volume of plasma, serum or packed blood cells is pipetted slowly into 5 volumes of 50% (by volume) acetone-alcohol, then brought to the boil and the supernatant filtered. The precipitated protein is extracted twice with 2.5 volumes of boiling acetone-alcohol. (With finely minced tissue, overnight extraction is repeated until extracts are colorless.) The combined filtrates are reduced to the original volume (hydrolyzed when desired) and extracted with 2 volumes of CCl_4 . An aliquot of this extract (equivalent to 5 cc plasma) is dried, dissolved in 5 cc benzene and chromatographed on alumina according to the technique described for urine extracts (*Federation Proc* 8: 180, 1949). Cholesterol and its esters are neatly separated from each other and from at least some other components which give color in the Liebermann-Burchard reaction. This technique shows some promise of providing simple determinations of cholesterol and of its esters in blood and tissues. Desoxycorticosterone and bis-dehydrodissynolic acid-7-methyl-ether are eluted readily from alumina by water. As compared with blood of normals, the blood of a patient with an adrenal tumor contained an increased amount of an easily eluted component. This was eluted in the same order as was the component previously reported (*ibid*) as increased in the tumor and in the acid hydrolyzed urine of a patient preceding (but not after) surgical removal of a hirsutizing adrenal tumor.

Rat growth experiments with some derivatives of phenylalanine MARVIN D. ARMSTRONG AND JOY D. LEWIS (introduced by V. DUVERGNEAUD) *Univ of Utah College of Medicine, Salt Lake City, Utah*

The metabolism of some compounds structurally related to phenylalanine has been studied by the use of the growth technique. The more readily prepared diastereoisomer of β -phenylserine, reported some time ago to be at least partially converted to benzoic acid *in vivo*, was examined for its ability to form either tyrosine or phenylalanine; it was found to be neither toxic nor beneficial when added to diets deficient in either of these amino acids. As would be expected from enzymatic

studies previously reported in the literature, glycidyldehydrophenylalanine is readily available as a precursor for phenylalanine in the diet and acetyldehydrophenylalanine cannot serve as a precursor of either phenylalanine or tyrosine when administered either by feeding or intraperitoneal injection. The effects of the isomeric 2-, 3-, and 4-fluorophenylalanines on the growth of young rats was studied and the acute toxicity of 3-fluorophenylalanine (BOYER, EVANS AND PHILLIPS, *J Pharmacol & Exper Therap* 73: 176, 1941) was confirmed. The 2-, and 4-fluorophenylalanines likewise are toxic but to a much lesser degree than the 3-fluoro isomer. Possible explanations for these toxicities will be discussed.

Lipide phosphorylation by surviving slices of the liver of rats on various diets CAMILLO ABTOM AND MARJORIE A. SWANSON * *Dept of Biochemistry, Bowman Gray School of Medicine, Winston-Salem, N C*

Slices prepared from the livers of rats previously maintained on various diets were incubated aerobically in the presence of labelled Na_2HPO_4 . The incorporation of P^{32} into the phospholipides by liver slices from animals maintained on a 5% casein diet was much lower than the incorporation by the livers of rats on a stock diet containing 25% proteins of mixed origin. This decreased synthesis of phospholipides seems due to the low protein level rather than specifically to a deficiency of choline or choline precursor in the diet of the animals. Indeed, supplementation of the low casein diet with choline did not raise the synthesis of phospholipides, whereas an increase in the casein content of the diet to 25% increased the rate to that found in the livers of rats on the stock diet. Addition of choline *in vitro* caused a marked inhibition of the phospholipide synthesis by the livers of rats on the high protein diets, whereas a certain degree of stimulation was obtained, when choline was added to the slices prepared from the livers of rats on the low protein diet. The effects of the *in vitro* addition of ethanolamine were similar, although less marked and less consistent. Betaine added to the surviving slices generally enhanced lipide phosphorylation, irrespective of the previous dietary regime of the animals.

Influence of vitamin B_{12} on a succinylsulfathiazole-induced dietary deficiency in rats CONRADO F. ASENJO *Dept of Chemistry and Nutrition, School of Tropical Medicine, Univ of Puerto Rico, San Juan, P R*

In the course of investigating the suppletory action of natural products on folic acid-deficient rats receiving a highly purified basal diet containing succinylsulfathiazole, it was noticed that many of the products tested induced a growth

response and a leukocyte regeneration at rates well above those obtained with the optimal level of folic acid. This suggested that the depleted animals suffered not only from a severe folic acid deficiency but also, perhaps, from other less severe deficiency, or deficiencies. As such a basal diet could have possibly developed a vitamin B₁₂ deficiency concurrently with the severe folic acid deficiency, it was decided to study the effect that B₁₂ supplementation could have in the depleted rats. Preliminary evidence indicates that when high levels of folic acid are given as supplement, the concurrent administration of vitamin B₁₂ significantly improved the growth-response and white cell count. At low levels of folic acid supplementation, the addition of B₁₂ did not improve the response produced by folic acid alone, though survival was a little longer. Folic acid negative controls receiving B₁₂ did not show any improvement, but they also lasted longer than the controls without B₁₂. The incidence of infarct-like splenic lesions was high in both groups of controls, in those receiving B₁₂, perhaps because they survived longer, the splenic lesions developed to such an extent that this organ was found, in several instances, adhered to those adjacent. A level of 0.5 µg/day of B₁₂ was used throughout.

Detection and identification of metabolites in tissues by means of paper chromatography
 JORGE AWAPARA (introduced by HARRY J. DEUEL, JR.) *Univ. of Texas, Anderson Hospital for Cancer Research, Houston*

Paper chromatography has been used as a quantitative method for some amino acids which are completely resolved by this procedure. The appearance of several unidentified components in chromatograms from tissue extracts has led to a system of isolating those components by means of paper chromatography, in sufficient quantity to allow identification. Thus far, ethanolaminophosphoric ester has been identified in nearly all organs of the rat and some human tumors. Presently, a peptide has been detected in many organs and in blood and an unidentified amino acid in brain only. The identification of the latter is under way.

Mild dephosphorylation of pyrimidine nucleotides
 JAMES E. BACHER* AND FRANK WORTHINGTON ALLEN *Dept. of Biochemistry, Univ. of California Med. School, Berkeley*

Existing methods for the hydrolysis of pyrimidine nucleotides require strenuous conditions and lead to partial destruction of the organic radicals. In an attempt to circumvent such destruction, the following procedure was devised. To a solution of pyrimidine nucleotide is added a 4-fold m excess of La(NO₃)₃. The pH is adjusted to 10 by the addition of NaOH. The suspension is heated at 100° for 2 hours. The pyrimidine nucleosides from

uridylic acid and from cytidylic acid have been recovered in approximately 95% yields and identified by the use of a Craig counter-current distribution apparatus and the ultra-violet spectra. The method of Fiske and Subbarow for the determination of phosphate cannot be applied directly to the hydrolysates. The procedure for hydrolysis is expected to aid in the preparation and analysis of the pyrimidine constituents of ribonucleic acids.

Spectrophotometric microdetermination of methionine, based on its reversible reaction with iodine (Lavine)
 BOHDAN BAKAY* AND GERRIT TOENNIES *Inst. for Cancer Research and Lankenau Hospital Research Inst., Philadelphia, Pa.*

Among amino acids methionine is distinguished by a reversible reaction with iodine, which can be abolished by oxidation with iodate (LAVINE, *J. Biol. Chem.* 151:281, 1943). The analytical application of this principle has been modified by replacing thiosulfate titrations with spectrophotometric determination of iodine, combined with solvent extraction. Adequate determinations (precision 1-2%) on undecolorized hydrolysate samples containing 50-100 micrograms of methionine are thus possible. In one pair of calibrated test tubes a blank and a 5 cc. aliquot of unknown solution are allowed to react with iodine at pH 7, the excess iodine is extracted with amylalcohol-carbon tetrachloride, and the colors of the aqueous layers are determined. The color of the blank tube represents residual iodine, and that of the unknown, iodine and hydrolysate color. Their difference (A) represents the effect of the unknown. The aqueous phases are then acidified. The difference between the two tubes at this stage (B) represents the value (A) plus the iodine liberated. Therefore, B minus A represents the reversibly bound iodine, i.e., methionine and substances reacting similarly. In another pair of tubes, blank and aliquot are first oxidized by iodate, and then the previous procedure is applied, yielding net color before acidification (C), and net total color following acidification (D). D minus C represents iodine bound reversibly after oxidation with iodate, i.e., substances other than methionine. (B - A) - (D - C) thus yields the methionine value. Details of technique and results obtained in the analysis of proteins and liver extracts will be presented.

Transfer of purines and pyrimidines from bacterial host to bacteriophage progeny
 J. MICHAEL BARRY, MIRIAM GOLUB BANKS AND ARTHUR L. KOCH (introduced by E. A. EVANS, JR.) *Dept. of Biochemistry, Univ. of Chicago, Chicago, Ill.*

Radioactive adenine, guanine, and thymine have been isolated from *E. coli* grown on ammonium lactate medium supplemented with NaH¹⁴C₃O₃.

and used for studying the transfer of bacterial purines and pyrimidines to bacteriophage progeny. *E. coli* cells can be specifically labeled in the purine fraction by culturing them on an ammonium lactate medium supplemented with C^{14} -labeled adenine, in which case both the adenine and guanine of the cells are labeled and account for all the radioactivity of the whole bacteria. Close to 100% of the adenine and guanine of the bacteria is derived from the adenine of the medium. Analysis of the bacteriophage T₂ grown on these specifically labeled bacteria demonstrates that almost one-half of the phage purines is derived from bacterial host purines. Analogous experiments with C^{14} -labeled guanine and thymine have also been carried out.

Transamination and total free amino acid carboxyl nitrogen in induced states of growth

PAUL D. BARTLETT (introduced by OLIVER H. GAEBLER) *Edsel B. Ford Inst. for Med. Research, Henry Ford Hospital, Detroit, Mich.*

The importance of transamination in the dynamic state of amino nitrogen has been emphasized in a number of studies on protein metabolism. Since nitrogen storage induced by the administration of growth hormone is accompanied by changes in plasma amino acid concentration, it seemed of interest to study the process of transamination and the concentrations of amino acids in tissues obtained from animals in which growth had been arrested by hypophysectomy or induced by the administration of growth hormone. Transaminase activity was determined in tibialis anticus homogenates of pair-fed rats by the method of Ames and Elvehjem (*J. Biol. Chem.* 166: 81, 1946). High activity in normal adult female rats was practically unaffected in states of induced growth. Activity was somewhat lower in rats hypophysectomized at 26–28 days of age and growth hormone treatment reduced it to the level of rapidly growing normal rats fed *ad lib*. Q_T^{10} values for each of the described groups were respectively +317, +313, +297, +256, and +250/mg of homogenate nitrogen. Total free amino acid carboxyl nitrogen analyses on pooled leg muscle for each of the groups of 3 to 6 rats gave values of 19.5, 18.5, 24.3, 27.9, and 28.1 mg %. Free amino acid concentrations in pooled muscle obtained from hypophysectomized rats in induced states of growth and from rapidly growing normal rats were thus found to be higher than in states of arrested growth and appear to be inversely related to the transaminating capacity of the tissue.

Sex differences in response to alloxan

ELIOT F. BEACH, PHOEBE J. BRADSHAW* AND N. R. BLATHERWICK *Biochemical Lab., Metropolitan Life Insurance Company, New York City*

Mature albino rats were fasted 4 days and then

injected subcutaneously with 20 mg alloxan monohydrate/100 gm body weight after which food was given. To determine the effects of alloxan on blood sugar during the first 48 hours groups of rats were studied at intervals to explore the significant fluctuations. The extent of permanent alteration in glucose economy was evaluated by running oral glucose tolerance tests on each animal before and 2 weeks following alloxan and by postprandial blood sugar and urinary glucose and acetone excretion tests after 1 and 3 weeks. These tests reveal marked individual variations in response to alloxan with the females of our strain reacting more violently and developing more severe permanent distortions of carbohydrate metabolism than the males. During the early 'triphasic' response more severe hyperglycemia, followed at 20–30 hours by much deeper hypoglycemia, has been observed in the females. Of 40 females examined to date 10 developed fatal acidosis, hyperglycemia and glycosuria compared with only 3 of 40 males. Fifty per cent of the males and only 17.5% of the females treated with alloxan failed to develop persistent glycosuria. The severely glycosuric females, when compared with the severely affected males, were characterized by greater distortions in oral glucose tolerance, higher fasting blood sugars and more frequent acetonuria.

Pool of miscible uric acid in the gouty human.

JEAN D. BENEDICT,* PETER H. FORSHAM,* MARCEL ROCHE,* SIDNEY SOLOWAY* AND DEWITT STETTEN, JR. *Division of Nutrition and Physiology, Public Health Research Inst. of The City of New York, Inc., Med. Clinic, Peter Bent Brigham Hospital, Boston, and Dept. of Medicine, Harvard Med. School, Boston, Mass.*

The magnitude of the pool of uric acid which mixes promptly with, and dilutes, tracer doses of intravenously injected isotopic (N^{15}) uric acid has been measured in the gouty human subject and has been found to exceed normal values by as much as 25-fold. Subsequent to the uric acid diuresis produced in the gouty subject by protracted salicylate therapy, this pool has been observed to contract to about $\frac{1}{5}$ of its initial value without the occurrence of any marked change in the level of serum uric acid concentration. This contracture has been ascribed to the loss by the patient of that portion of the urate initially present in the solid phase which is rapidly miscible with uric acid in solution. Whereas therapeutic doses of colchicine were without demonstrable effect upon the quantities measured, the administration of ACTH, in an acute experiment, was followed by the expected diuresis of uric acid. Since this effect was accompanied by a fall in the serum uric acid concentration and no change in the rate of dilution of

isotope, it is provisionally concluded that the site of this action is at the level of the renal tubule

Metabolism of intravenously administered N^{15} -labeled compounds MAX BERENBOM* AND JULIUS WHITE *National Cancer Inst, National Insts of Health, Bethesda, Md*

Comparative studies have been made of the metabolism in rats, after intravenous administration of N^{15} -labeled ammonium glutamate (labeled in the ammonium ion), glutamine (labeled in the amide group), glycine, and L-phenylalanine, by following the 24 hour urinary excretion of N^{15} . Normal rats (200-220 gm) injected with an aqueous solution of ammonium glutamate, glutamine, glycine, or L-phenylalanine, equivalent to 5 mg of labeled nitrogen/rat, excreted 66, 66, 38, and 40% of the N^{15} respectively. Similar results were obtained when the amount of ammonia or glycine was increased to 15 mg of labeled nitrogen/rat. Young, growing rats (100-110 gm) each receiving 2.5 mg of labeled nitrogen, and rats (original weight 200-220 gm) fasted for 5 days and then each injected with 5 mg of labeled nitrogen, in the form of one of the above mentioned compounds, excreted approximately the same percentage of administered N^{15} as the normal rats. In all these experiments approximately 90% of the excreted N^{15} was recovered as urea and 2-8% as ammonia. Although the percentage of administered N^{15} excreted as ammonia was small, during the first hour a relatively large fraction of the total ammonia excreted was derived from the injected compounds.

Isolation of β -glucuronidase of calf spleen and factors influencing its activity PETER BERNFELD* AND WILLIAM H. FISHMAN *Cancer Research and Cancer Control Unit, Depts of Surgery and Biochemistry, Tufts College Med School, Boston, Mass*

Glucuronidase from calf spleen has been purified by several ammonium sulfate fractionations, mainly in an alkaline medium. A highly active enzyme has been obtained which behaves like a single protein in the electrical field at pH 4.2 and 8.6. The pure glucuronidase has an isoelectric point between pH 7.5 and 8.0 and an activity optimum at pH 4.5. During this purification, several fractions with lower glucuronidase activity have been discarded, but no fraction has been obtained showing a different pH optimum. A marked shift of the pH optimum of the pure glucuronidase to pH 5.0 or more, accompanied by a change in its activity, can be observed after addition of saccharate, gluconate, adenylate or of a non-protein fraction obtained from calf spleen. It is believed that the alkaline fractionation removes such or similar acid compounds which otherwise always

accompany the protein in an acid precipitation. This explains the observation made by other authors that several glucuronidases with different pH optima can be obtained by fractional salt precipitations in an acid medium. The existence of only one glucuronidase in calf spleen is confirmed by the identical ratio of the velocity of hydrolysis observed with two different substrates (phenolphthalein-glucuronide and menthol-glucuronide) for all fractions obtained during the purification. The activity of pure glucuronidase at pH 4.5 is increased 50% by 0.5% ribonucleate and 120% by 0.5% desoxyribonucleate. The activity of glucuronidase in tissue would appear to be greatly determined by the desoxyribonucleate present.

Effect of ACTH and other substances on the lipid metabolism of rat brain FREDERICK BERNHEIM AND HOWARD L. ZAUDER* *Dept of Physiology and Pharmacology, Duke Univ Med School, Durham, N C*

When brain homogenates are incubated aerobically and then precipitated with trichloroacetic acid, the filtrate heated with thiobarbituric acid produces a red color. It has been shown that an oxidized form of linolenic acid reacts with the thiobarbituric acid to form the colored product. The *in vitro* addition of ascorbic acid before incubation increases the values. When rats are injected with either ACTH or adrenal cortical extract some time before the removal and incubation of the brains, large increases in values are obtained both with and without the addition of ascorbic acid. A number of analgesic drugs such as morphine, meperidine, methadon and adrenaline produce similar effects.

Loss of body potassium during pergastric intestinal perfusion LIONEL BERNSTEIN,* PHILIP B. O'NEILL,* ARTHUR BERNSTEIN* AND WILLIAM S. HOFFMAN *Hektoen Inst for Med Research, Cook County Hospital, Chicago, Ill*

Perfusion of the entire intestine was carried out in 9 human subjects with preterminal uremia. The perfusing fluid contained 148 or 143 mEq sodium, 5 or 10 mEq potassium, 3 mEq magnesium, 105 mEq chloride, 51 mEq bicarbonate, and 2% glucose. The fluid was perfused through a stomach tube at a rate of approximately 2 l/hour and collected from the rectum. The gastric perfusate was also collected by suction. At the end of 8-12 hours the potassium loss from the body ranged from 2-12.7 gm. Since the total extracellular potassium was less than 3 gm, the greatest part of the lost potassium came from the cells. In all cases there was a significant drop in serum potassium concentration, in 2 instances to the pathologically low level of 3.0 mEq/l. But the serum potassium concentration could not be predicted

from the total potassium loss. The fluid obtained from the rectum had potassium concentrations ranging from 11.3–26.0 mEq/l, or from 2–7 times as high as the serum potassium concentration. Even when the perfusate contained 10 mEq/l, the potassium balances were negative. The passage of potassium from body fluids to perfusate was therefore not due to simple dialysis. But the exact mechanism involved is not clear.

Effect of amino acids on the non-enzymatic decarboxylation of oxalacetic acid. SAMUEL P. BESSMAN (introduced by JOSEPH H. ROF) *Research Foundation of Children's Hospital, Washington, D. C.*

Amino acids in concentrations approximating the total amino acid content (as equivalents of alpha amino nitrogen) of normal tissues have been found to stimulate the decarboxylation of oxalacetic acid (OAA) from 2–18 times the spontaneous rate. Conditions were acetate buffer 0.10 M, pH 5.0, temperature 37°C, OAA approximately 0.07 M, amino acid tested usually 0.05 M, in total volume of three ml. A freshly prepared solution of OAA was placed in the sacs of the Warburg flasks and the reaction was begun by tipping after a period for temperature equilibration. It was found that almost all of the amino acids stimulated the breakdown of OAA as a first order reaction with respect to OAA. The most active amino acids tested were L(+) histidine (186), DL ornithine (078), L(+) lysine (050), glycine (049), and L(+) arginine (045), the numbers in parenthesis representing the first order reaction constant expressed in reciprocal minutes. The constant for our preparation of OAA was 0.10 min^{-1} . Acetylation diminishes the activity of glycine and glutamic acid, and the amides of the dicarboxylic acids are more active than the parent amino acids. Since the tissue concentration of amino acids is sufficient to cause at least a doubling of the rate of OAA breakdown and since the stimulation is proportional to the concentration, these results suggest a physiological role of amino acids in the regulation of carbohydrate oxidation, thus offering another approach to the problem of gluconeogenesis.

Influence of choline and inositol upon the rate of deposition and removal of liver lipids. C. H. BEST, C. C. LUCAS, JEAN M. PATTERSON* AND JESSIE H. RIDOUT *Banting and Best Dept. of Med. Research, Univ. of Toronto, Toronto, Canada*

Assessment of the lipotropic activity of inositol has sometimes been complicated by the presence of choline in the basal diet and by inadequate dietary protein. The rate of change of total liver lipids and cholesterol under the influence of 1) an improved basal diet alone, 2) plus supplementary inositol alone, 3) plus choline alone, and 4)

with choline plus inositol, has been measured by analyzing livers of animals fed the test diets for periods of 3, 5, 7, 9, 14, 21 and 28 days, respectively. Rats (Wistar strain, weighing 70–100 gm) were depleted of B vitamins by feeding for 3 weeks a fat-free hypolipotropic diet consisting of casein 10, arachin 2, fibrin 2, salts 4, cellulose 2, sucrose 80, cod liver oil concentrate 0.015%. After the depletion period the rats were divided into groups and were fed the test diets (containing liberal amounts of all the commercially available B vitamins) for the periods mentioned. A similar experiment was conducted in which fat was present (12% replaced an equal amount of sucrose) in the diets during both depletion and test periods. When liver lipids were plotted against time the 7-day test period, which has been frequently used, was found to be unsuitable. This period is one of rapid change rather than of equilibrium. Inositol alone, even at maximal effective dosage, has only a limited lipotropic effect in fat-free diets and none in diets containing fat.

Thionase activity. FRANCIS BINKLEY *Univ. of Utah College of Medicine, Salt Lake City*

Preparations of purified thionase, activated with glutathione, have been found to attack a wide variety of S-substituted cysteines. The S-methyl, ethyl, propyl and butyl derivatives are attacked with the formation of neutral mercaptans identified as methyl, ethyl, propyl and butyl mercaptans respectively. The S-carboxymethyl and carboxyethyl derivatives are attacked at a low rate with the formation of acidic mercaptans. The methyl ester of cysteine and cysteinylglycine are cleaved without preliminary hydrolysis and with the formation of hydrogen sulfide. Djenkolic acid is cleaved with the apparent formation of cysteine. Certain of the above results have been checked as to whether or not the compounds will provide cysteine for the growth of the white rat. Frozen pig kidney has been found to be a suitable source of the enzyme but no activity is observed unless glutathione is added. Certain evidence has indicated the presence of a coenzyme. The purified enzyme may be dissociated into dialyzable and non-dialyzable components. The dialyzable component has a characteristic spectrum in the ultraviolet and is destroyed by heat-labile components of various tissues.

Effect of colchicine and cortisone on uric acid metabolism in gout. CHARLES BISHOP, WILLIAM GARNER AND JOHN H. TALBOTT (introduced by WILSON D. LANGLEY) *Dept. of Medicine, Univ. of Buffalo Med. School and Buffalo General Hospital, Buffalo, N. Y.*

Certain aspects of uric acid metabolism in patients with gout and other diseases are being studied in this laboratory using heavy nitrogen.

Uric acid with N¹⁵ in the 1,3 positions was injected intravenously into gouty individuals during gouty attacks both before and after therapy with colchicine or cortisone. Excreted uric acid was isolated as the ammonium salt from 6 hour samples of urine. Pool size and turnover rate were calculated by the method of Stetten (*J Biol Chem* 181:183, 1949). In one gouty patient with a uric acid pool size of 3300 mg (approximately 3 times normal), colchicine caused a 50% decrease in the pool size and an increase in the turnover rate from 0.50 to 1.01 pools/day. Another gouty patient with a comparable pool size demonstrated after cortisone therapy a 30% decrease in the pool size along with an increase in the turnover rate from 0.59 to 1.26 pools/day. A third gouty patient showed no metabolic response to either of these drugs even though his uric acid pool size was comparable to those of the other two patients studied. This latter patient, however, had been maintained on a small daily dose of colchicine for some time. The implications of these findings will be discussed.

Comparison of various techniques for hydrolysis of conjugated 17-ketosteroids in urine JOEL BITMAN* AND SAUL L. COHEN *Dept of Physiological Chemistry, Univ of Minnesota Med School, Minneapolis*

A technique for the hydrolysis of a relatively labile group of 17-ketosteroid conjugates by weakly acidic buffers was previously reported (*Federation Proc* 8:184, 1949). The 17-ketosteroids thus released contain a high percentage of 3-beta hydroxy compounds (40-60%). The hydrolysis of 17-ketosteroid conjugates with an ox spleen β -glucuronidase preparation has been found to release approximately 50% of the ketosteroids in urine. Glucuronidase hydrolysis releases 17-ketosteroids with a relatively low 3-beta hydroxy steroidal content (3-7%). Evidence that the buffer hydrolyzed conjugates are sulfates has been obtained through 1) a comparison of the buffer technique with the mild hydrolytic procedures of other workers, 2) the complete hydrolysis by this technique of pure sodium dehydroisoandrosterone sulfate, and 3) the non-effectiveness of the buffer treatment in hydrolyzing the glucuronide linkage or of the glucuronidase treatment in hydrolyzing the sulfate linkage. It has been found possible to hydrolyze $\frac{3}{4}$ to $\frac{1}{2}$ of the conjugated 17-ketosteroids of normal male urine by the use of a combination of these procedures. The remaining conjugated 17-ketosteroids which were not released by the treatments thus far attempted can be hydrolyzed by the usual HCl treatment. The combined use of buffer and enzyme techniques obviates to a great degree the destructive effects of strong acid hydrolysis.

Formation of acetate from acetaldehyde in cell-free yeast extracts SIMON BLACK *Chemical Division, Dept of Medicine, Univ of Chicago, Chicago, Ill*

Two extracts of bakers' yeast have been prepared which catalyze the simultaneous formation of acetate and ethanol from acetaldehyde. An extract of rapidly dried (1 minute) Fleischmann's yeast, after dialysis against a non-phosphate buffer, requires for its catalytic action DPN, inorganic phosphate, magnesium ions, and cystein. Under certain conditions a small accumulation of a labile phosphate can be demonstrated after incubation with acetaldehyde. An extract of frozen (liquid N₂) Red Star yeast loses its activity irreversibly on dialysis against a non-phosphate buffer. When dialyzed over-night against phosphate its activity is dependent upon DPN, magnesium ions, and an additional unidentified factor present in a yeast 'kochsaft'. The latter is prepared from a briefly dialyzed (2-3 hours with stirring) preparation of the enzyme extract. The activity of the Red Star extract is greatly increased by heating to 50° for 15 minutes. Its activity also increases markedly on storage for 1-3 days at 2° or -10°, but 1 week at either of these temperatures results in complete inactivation. The activity of both extracts remains in the supernatant when centrifuged at 15,000 r.p.m. A colorless, clear solution of the Red Star enzyme has been prepared by fractionation with acetone.

Demonstration and comparison of two glycogen fractions in liver and muscle WALTER LYON BLOOM,* MARY SCHUMPERT* AND GEORGE T. LEWIS *Dept of Biochemistry, Emory Univ School of Medicine, Emory University, Ga*

There has been considerable speculation concerning the presence in tissues of 2 types of glycogen. No adequate method has been available for the separate determination of the 2 types and no physiological significance has been described for such fractions. This report presents a simple method of distinguishing 2 fractions of glycogen in tissue. The procedure depends on differences in solubility of the 2 fractions in trichloroacetic acid extracts of homogenized tissue. The results obtained with the method are easily reproducible and have a high order of statistical significance. The 2 glycogen fractions have been shown to be present in the liver and muscle of rabbits and rats. The liver of the fed animal contains more of the acid soluble fraction (85% of the total) than the muscle (55%). Adrenaline has been shown to most markedly influence the removal of the acid-soluble fraction of muscle glycogen, and it is suggested that this fraction is the most physiologically labile component of the glycogen present in liver and muscle.

Minor role of non-hepatic tissues in plasma protein synthesis observed with the aid of lysine- α - C^{14} C G BLY,* L L MITTER AND W F BAILE Depts of Radiation Biology and Pathology, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y

The surviving carcasses of normal Wistar strain rats, posterior to the second lumbar vertebra, with or without kidneys, has been found to synthesize plasma globulins from a complete mixture of amino acids containing DL lysine α - C^{14} . Although the amino acids are rapidly removed from the continuously perfused heparinized blood, the total plasma protein synthesized amounts to 5-20% of that synthesized by the liver from the same amino acid mixture in the same time (MITTER, L L, C G BLY, M L WATSON AND W F BAILE *Federation Proc*, this issue) Weight for weight, the liver is at least 200 times as active as the carcass in plasma protein synthesis. On a relative basis the skeletal muscle, kidney, and testes have produced far more tissue protein than plasma protein. The liver, on the contrary, synthesizes an amount of plasma protein of the same order of magnitude as that of the liver tissue protein.

Influence of α -amino acids on rate of enzymic conversion of phosphorylated compounds OSCAR BODANSKY, OLGA BLUMENFELD,* ELAINE ZINKER* AND BLANCHE MARKARDT *Memorial Hospital and Sloan-Kettering Inst for Cancer Research, New York City

The extent and nature of the inhibition of phosphatase hydrolysis of Na β -glycerophosphate by α -amino acids have been previously reported (BODANSKY, *J Biol Chem* 179 81, 1949, 174 465, 1948). In the present study, similar inhibition was shown to exist for the dephosphorylation of ATP and fructose-L,6-diphosphate by intestinal and bone phosphatase preparations. However, α -amino acids accelerate the dephosphorylation of ATP by fresh tissue homogenates at pH 7.4 and of fructose-L,6-diphosphate by liver hexosediphosphatase at its alkaline optimum. Acceleration of dephosphorylation of ATP by α -amino acids is greatest in skeletal muscle homogenates, but also occurs to some extent in cardiac, liver, brain and kidney homogenates. In extension of Sutherland's finding that enzymic conversion of glucose L-phosphate to glucose-6-phosphate is activated by metal-binding agents (*J Biol Chem* 180 1279, 1949), a number of α -amino acids were found to accelerate this reaction, the degree of acceleration being dependent on the nature and concentration of the α -amino acid. Hexokinase activity was affected only negligibly by α -amino acids at pH 7.4. Incubation of skeletal muscle homogenates with Co^{++} , Zn^{++} , Mn^{++} , Ni^{++} or Cu^{++} resulted in marked inactivation of the dephosphorylation of

ATP, and such activity was restored to varying extents by the addition of histidine. Data are also presented concerning the relationship between the effects of α -amino acids and the effects of metal ions for osteogenic sarcoma phosphatase, liver hexosediphosphatase, phosphoglucomutase, and hexokinase.

Studies on metabolism of 3-hydroxyanthranilic acid ANN H BOKMAN* AND B S SCHWEIGERT Division of Biochemistry and Nutrition, American Meat Inst Foundation, and Dept of Biochemistry, Univ of Chicago, Chicago, Ill

During investigations on the enzymatic destruction of 3-hydroxyanthranilic acid, an intermediate in the formation of nicotinic acid from tryptophan, it was found that this compound fluoresces, and that the fluorescence observed was a linear function of the concentration. The fluorescence of 3-hydroxyanthranilate was found to vary with the pH, and a pH of 7.0 was found to be optimum. Quinolinic acid, nicotinic acid, and N'-methyl-nicotinamide do not fluoresce under the conditions used for measuring 3-hydroxyanthranilic acid, and 3-hydroxyanthranilate could be quantitatively recovered in the presence of heat inactivated rat liver homogenates and solutions of acetone dried powders of liver. Experiments were performed both with rat liver homogenates, and with solutions of acetone dried powders of rat liver, in which 3-hydroxyanthranilic acid, buffer, and enzyme solution were incubated together at 37° and at pH 7.4 for various time intervals. It was found that the conversion of the substrate to non-fluorescent products was proportional to the enzyme concentration, and that with the enzyme concentration constant the conversion of substrate was proportional to the amount added until the enzyme became limiting. Coupled with these experiments, microbiological determinations of nicotinic acid before and after acetic acid treatment of the incubation mixtures were made and the conversion of 3-hydroxyanthranilate to quinolinic acid equivalent to 86 to 100% on a molar basis was found. These values were in accord with the amounts of substrate converted to non-fluorescent products by the test systems.

Potassium compounds associated with carbohydrate metabolism of *Escherichia coli* E T BOLTON (introduced by J B ALLISON) Dept of Terrestrial Magnetism, Carnegie Inst of Washington, Washington, D C

Studies of uptake and loss of potassium by *E coli* as well as studies of the metabolism of potassium-deficient cells have indicated the existence of potassium compounds in the cell. Since these compounds dissociate fairly readily in aqueous solution it is difficult to identify them by conventional chemical procedures. By means of paper

chromatography and radioactive tracer methods, however, it is possible to demonstrate potassium compounds in extracts of *E coli*. Comparisons of chromatograms of extracts of cells grown in the presence of K^{42} with known samples reveal the existence of compounds which show the same movement in a butyl-alcohol-acetic acid-water solvent as the K-salts of hexose phosphates. These compounds account for a large fraction of the total potassium in the cell. The biological origin of these compounds is further demonstrated by control experiments with non-radioactive cell extracts. These findings confirm the work of others in this laboratory who have shown that potassium is associated with the metabolism of hexose phosphates.

N^{15} Studies on conversion of tryptophan to niacin in neurospora DAVID M BONNER AND C W H PARTRIDGE * *Osborn Botanical Lab, Yale Univ, New Haven, Conn*

The scheme of niacin synthesis in neurospora involving tryptophan is largely predicated on mutant strains of one genetic type. Since certain observations regarding such strains are not readily reconcilable with the thesis that tryptophan serves as a major niacin precursor, a direct check of the conversion of indole to niacin has been made. Strain 10575 requires tryptophan or indole for growth, accumulates anthranilic acid, but cannot grow on niacin. Since the only source of tryptophan available to this strain is that added, the formed niacin should reflect the same N^{15} content as the indole used for culture if tryptophan conversion represents a major pathway of niacin synthesis. For ease of isolation, a double mutant was formed with 10575 and a strain known to accumulate generous quantities of quinolinic acid (BONNER AND YANOFSKY, *Proc Nat Acad Sci* 35 576, 1949). This double mutant was cultured on indole having 3.97 atom % excess N^{15} . After growth, the quinolinic acid present in the medium was isolated and found to contain 2.98% excess N^{15} . The anthranilic acid accumulated during growth of this double mutant was also isolated and its N^{15} content determined as a direct check of the tryptophan cycle recently proposed by Haskins and Mitchell (*Proc Nat Acad Sci* 35 500, 1949). The anthranilic acid was found to contain no appreciable N^{15} . One may conclude, therefore, that in neurospora, anthranilic acid is not formed from tryptophan to an appreciable extent and that niacin formation from tryptophan represents a major synthetic pathway.

Inulin clearance during pregnancy ROY W BONS-
NES AND WILLIAM A LANGE * *Dept of Obstetrics
and Gynecology, Cornell Univ Med College and
New York Hospital, New York City*
According to data in the literature, pregnant

women have inulin clearances of the same order of magnitude as nonpregnant women. The subjects for these tests were, in the main, near term. A survey by us of this function throughout pregnancy shows 13 normal women 11-37 weeks pregnant to have significantly elevated inulin clearances which average 183 ml/min/1.73 m² with a standard deviation of the sample of ± 20 compared with 119 ± 4 for 8 nonpregnant controls. However, women 38 weeks or more pregnant were observed to have inulin clearances which average 129 ml/min/1.73 m², a value not significantly different from the control value and in agreement with the data in the literature. But the standard deviation of this sample is ± 43 , indicating quite a range of values. Both groups of pregnant women were observed to have changes in simultaneously performed urea and p-amino hippurate clearances which followed the inulin clearances in direction but not in magnitude.

Mechanism of bacterial growth inhibition by hydroxylamine ERNEST BOREK, NATHAN GROS-
SOWICZ* AND HEINRICH WAELSCH *Depts of Bio-
chemistry, New York State Psychiatric Inst and
Columbia Univ, New York City*

The recent discovery of an enzyme system (glutamo- and asparto-transferases) which exchanges the amide group of glutamine and asparagine with hydroxylamine suggested a possible mechanism for the inhibition of bacterial growth by hydroxylamine. The growth inhibition was studied on *Lactobacillus arabinosus* and on *Proteus vulgaris*, the latter organism can synthesize glutamic acid and also contains glutamo- and asparto-transferases, while the former is unable to synthesize the amino acid, and the presence of the enzyme system has not been demonstrated in it. In synthetic media containing amino acids the growth of *Proteus vulgaris* is inhibited completely by 3×10^{-4} molar hydroxylamine, while *Lactobacillus arabinosus* requires about 5 times the concentration of the inhibitor. The growth inhibition of both organisms is overcome by ammonia or glutamine, or any compound from which ammonia is easily liberated. The antibacterial index with both organisms is about 1. The relationship between hydroxylamine inhibition and its reversal can be studied only within a narrow range of concentrations of the inhibitor, since a high concentration of hydroxylamine interferes with the utilization of other metabolites (keto acids, etc). These findings suggest that hydroxylamine may interfere with the formation and utilization of asparagine or glutamine.

Incorporation of C^{14} -labeled amino acids into proteins of fractions of guinea pig liver homogenate HENRY BORSOOK, CLARA L DEASY,*
ARIE J HAAGEN-SMIT,* GEOFFREY KEIGHLEY*

AND PETER H. LOWE * *Kerckhoff Labs of Biology, California Inst of Technology, Pasadena, Calif*

Three different particulate fractions and a supernatant fraction of guinea pig liver homogenate were prepared by differential centrifugation. The four fractions exhibited functional differences in the rates at which they incorporated glycine, histidine, L-leucine or L-lysine. L-lysine was incorporated into the proteins of the particulate fractions under one set of conditions and into those of the supernatant fraction under another set of conditions. Evidently the incorporation of amino acids into proteins *in vitro*, does not, in the adult cell, necessarily depend on direct participation of the nucleus. One hour after the intravenous injection of guinea pigs with 20 mg of labeled amino acid/kg the incorporation of glycine, histidine, leucine or lysine into the liver proteins was of the same order of magnitude as in the most active liver fraction *in vitro*. Each of the 4 amino acids was incorporated into the proteins of all 4 fractions. The greatest uptake in every case was in the microsome fraction. *In vitro* this fraction was the least active, this may be because optimal experimental conditions have not yet been found for the *in vitro* experiments.

Characteristics of protease trypsin inhibitor of soy beans DONALD E. BOWMAN *Dept of Biochemistry and Pharmacology, Indiana Univ School of Medicine, Indianapolis*

Present evidence further supports the protease nature of the soy bean trypsin inhibitor to which we have called attention, which is soluble in 60% alcohol and 10% trichloroacetic acid. This inhibitor differs from the globulin soy bean trypsin inhibitor in many respects. A few of the properties of this protease are indicated by the method of preparation which involves extraction of previously unheated soy bean meal with 60% ethyl alcohol, precipitation with acetone or increased alcohol, precipitation of inert material and any remaining globulin inhibitor with trichloroacetic acid, precipitation of the active material with 5% saturated ammonium sulfate and dialysis. Intravenous administration is effective in diminishing fatal pulmonary and cardiac embolism which results from the injection of small amounts of trypsin in rabbits. It also inhibits the trypsin-like protease of plasma but, like other trypsin inhibitors, it is less effective against the thromboplastic and proteolytic activities of iodinated trypsin than it is with untreated trypsin. It does not prevent the hypotensive effect of intravenous trypsin. Rabbits do not appear to become sensitized to this inhibitor. Further evidence indicates that there are various bean trypsin inhibiting fractions as we have emphasized since first calling

attention to bean enzyme inhibitors. One fraction, also having protease characteristics, is quite similar to the material used in the present work except that it is insoluble in trichloroacetic acid at room temperature.

Further properties of a tuberculostatic fraction of human plasma DONALD E. BOWMAN *Dept of Biochemistry and Pharmacology, Indiana Univ School of Medicine, Indianapolis*

A fraction of autoclaved human plasma which retards the growth of the H-37 strain of tubercle bacilli has characteristics of a lipid. It is soluble in alcohol, ether and acetone. It can be concentrated by direct ether extraction of autoclaved plasma or inert material can be precipitated from an aqueous extract of the autoclaved plasma with 90% ethyl alcohol at low temperatures with subsequent ether extraction of the residue of the evaporated alcoholic filtrate. It can be precipitated with ammonium sulfate and dialyzed. It inhibits the growth of the H-37 strain on undiluted sterile human plasma which has been coagulated with a minimum of heat. In the majority of instances growth readily occurs on such plasma in the absence of the activated inhibitor. The degree of inhibition is further estimated by determining the nitrogen content of the washed organisms grown in synthetic media. Observations suggest that the presence or the liberation of this heat stable substance *in vivo*, possibly through an enzymatic mechanism, may contribute to resistance to tuberculosis.

Biosynthesis of radioactive fatty acids and cholesterol ROSCOE O. BRADY* AND SAMUEL GURIN *Dept of Physiological Chemistry, Univ of Pennsylvania School of Medicine, Philadelphia*

We have studied the biological synthesis of long chain fatty acids and cholesterol by incubating slices of liver tissue from fed rats of the Wistar strain in the presence of C¹⁴-labeled acetate, pyruvate, butyrate, hexanoate, and octanoate as substrates. The usual procedures for the isolation of fatty acids and cholesterol were followed. Fatty acids whose chain lengths were longer than 10 carbon atoms were separated by precipitation with a copper-lime mixture and effectively freed from contaminating substrate. All of the substrates investigated contributed carbon atoms for long chain fatty acid and cholesterol synthesis *in vitro*. The addition of amorphous insulin to the incubating medium increased significantly the amount of acetate incorporated into long chain fatty acids. It would appear that all of the short chain fatty acids we investigated are as efficiently converted to long chain fatty acids as is acetate.

Metabolic competition of pyruvate and lactate in cardiac muscle slices MYRON C. BRIN AND

ROBERT E OLSON (introduced by FREDRICK J STARE) *Dept of Nutrition, Harvard School of Public Health, and Dept of Biological Chemistry, Harvard Med School, Boston*

Cardiac muscle slices from healthy ducklings 250-350 gm in weight fed an adequate diet *ad libitum* were incubated in Warburg vessels with pyruvate alone at levels of 1-5 mm/l, with lactate alone at levels of 1-5 mm/l and with lactate plus pyruvate with each varied from 1-5 mm/l, at 37° for one hour. Oxygen consumption was determined manometrically and changes in pyruvate and lactate levels during incubation determined chemically. In this range the utilization of pyruvate and of lactate was a function of initial concentration, pyruvate being used 20% more rapidly than lactate. With combinations of pyruvate and lactate as substrate, the total C₂-compound utilization was greater than that with each alone. Under these conditions, increasing concentrations of lactate had relatively little effect upon pyruvate utilization, whereas increasing concentration of pyruvate progressively decreased lactate utilization. Related isotope studies of the effect of each substrate upon the oxidation of the other will also be presented.

Some biological and chemical properties of the citrovorum factor HARRY P BROQUIST,* E L R STOKSTAD AND T H JUKES *Lederle Labs Division, American Cyanamid Company, Pearl River, N Y*

Recent studies have indicated that concentrates of natural materials active for growth of *Leuconostoc citrovorum* reverse the toxicity of folic acid antagonists for some microorganisms under conditions in which pteroylglutamic acid (PGA) is ineffective. In the present study further evidence for the ability of citrovorum factor (CF) concentrates to reverse 4-amino PGA for *L citrovorum* was found. In studies with mice it was found that CF concentrates given either in the diet or by injection could protect mice against the toxic effects of 4-amino PGA, PGA was without effect in alleviating this toxicity. In counter current distribution studies by the method of Craig, it was found that the distribution curves for CF activity or folic acid activity were indistinguishable. In other experiments it was found that CF was readily converted by exposure to HCl to a compound with properties similar to folic acid. These findings coupled with the ability of CF concentrates to reverse the toxicity of 4-amino PGA in microorganisms and mice support the view that CF is a hitherto unrecognized biologically active form of PGA.

Chronic exposure of adult mice to C¹⁴O₂ DONALD L BUCHANAN (introduced by SIMON BLACK)

Biology Division, Argonne National Lab, Chicago, Ill

Certain fractions of total carbon of tissues and of compounds in various organisms are derived from air CO₂. Such fixed carbon fractions have not been reported. If an animal is kept for an extended period in CO₂-labeled air the ultimate ratio of the specific activity (*s a*) of the carbon in a particular component to the *s a* of the atmospheric CO₂ should represent the fixed carbon fraction of the component. Mice were ventilated in 3 serially connected, sealed metabolism chambers with constantly flowing labeled air. Animals were sacrificed at intervals during a 34-day exposure and up to 45 days thereafter, and the *s a* of tissues and excreta measured. Although the C¹⁴O₂ content per unit volume of gas was equal in the three chambers, the total CO₂ concentration was not. Below 1.7% the CO₂ concentration had slight influence on C¹⁴O₂ retention. Hence, total retention of air CO₂ is proportional to its concentration below 1.7%. Urea carbon reached a constant *s a* within the first day while erythrocyte carbon failed to reach a constant level. Each of approximately 30 other components reached constant *s a* levels in 3-16 days. Fixed carbon fractions of various soft tissues varied between 10⁻⁴ and 3 × 10⁻⁵ at the normal air concentration of CO₂, while that for urea carbon was 3.5 × 10⁻³. All *s a*-time curves were more complex than the simple exponential except the erythrocyte curve which was linear. The latter showed the life span of the mouse erythrocyte to be 52 days.

Lipids of normal and pathological aortas R C BUCK* AND R J ROSSITER *Dept of Biochemistry, Univ of Western Ontario, London, Canada*

The concentration of free and total cholesterol (method of SCHOENHEIMER AND SPERRY, *J Biol Chem* 106 745, 1934) phospholipids (method of HACK, *J Biol Chem* 169 137, 1947) and total fatty acid (oxidative method of BLOOR, *J Biol Chem* 77 53, 1928) were determined in a number of normal and pathological human aortas. In aortas that appeared normal on macroscopic examination the concentration of total cholesterol and total phospholipid increased with age. From birth to 35 years the increase in cholesterol was confined chiefly to free cholesterol, the percentage of cholesterol in the ester form being low in these younger age groups. After 35 years the increase was chiefly in the ester fraction, the free cholesterol remaining fairly constant. An increase in the concentration of sphingomyelin accounted for all the increase in phospholipid with age. Cephalin, lecithin, or neutral fat (i.e. fatty acid other than in cholesterol ester or phospholipid) was not related to age. In aortas showing macroscopic evidence of atherosclerosis there was an increase in

the concentration of both free and ester cholesterol, total phospholipid and neutral fat, the increase in the concentration of these lipids being related to the severity of the lesion. Lecithin and sphingomyelin accounted for the increase in phospholipid. There was no increase in cephalin.

Hydrolysis of 17-ketosteroid conjugates HENRY J BUEHLER,* PHILIP A KATZMAN AND EDWARD A DOISY *Dept of Biological Chemistry, Saint Louis Univ School of Medicine, Saint Louis, Mo*

Our previous work has shown that bacterial glucuronidase effectively hydrolyzes steroid glucuronides. In a continuation of our studies on the hydrolysis of conjugated steroids, our attention has been focussed on the steroid sulfates. Attempts to obtain microbiological sulfatases have shown these enzymes to be highly specific but none has been found to hydrolyze the 17-ketosteroid sulfates. Refluxing aqueous solutions of sodium dehydroisoandrosterone sulfate or sodium androsterone sulfate with 15 volumes % of HCl for 10 minutes resulted in poor recoveries of both steroids. Longer periods of refluxing gave even poorer recoveries of androsterone and did not improve the recovery of dehydroisoandrosterone. Autoclaving for one hour at pH 7.3 (or higher) under 15 pounds pressure hydrolyzed the dehydroisoandrosterone sulfate almost completely but did not hydrolyze androsterone sulfate. This difference of behavior was also exhibited when the procedures of Talbot, *et al* and Bitman and Cohen for the hydrolysis of 17-ketosteroid sulfates were employed. Autoclaving at pH 7.3 produced no detectable hydrolysis of the glucuronides of estriol, menthol or phenolphthalein. Continuous extraction with ether for 24 hours at pH 0.7 or treatment by standing in 7.2 N HCl for 18 hours at 38°C effectively hydrolyzed both steroid sulfates. The glucuronides were not affected by continuous ether extraction at pH 0.7 but were hydrolyzed to the extent of 50% by the strong acid treatment. The application of these procedures to urine of normal men have shown that continuous extraction with ether at pH 0.7 liberated from 25-200% as much 17-ketosteroid as was liberated by glucuronidase hydrolysis.

Role of methionine as methyl donor for choline synthesis in the chick K A BURKE,* R F NYSTROM* AND B CONNOR JOHNSON *Division of Animal Nutrition and Radiocarbon Lab, Univ of Illinois, Urbana*

Methionine labeled in the methyl position with radiocarbon has been synthesized and fed to individual chicks. The expired CO₂ was collected at 1- to 8-hour intervals for the next 48 hours, after which the chickens were sacrificed and the choline isolated from the whole carcass. Radioactive carbon determinations made on the expired CO₂

and on the isolated choline showed both to contain C-14. Quantitative data on the oxidation of methionine-methyl groups and on the synthesis of choline from methionine-methyl groups will be reported. These findings bring the chick into conformity with the rat, man and pig.

Studies on metabolism of radioactive L-ascorbic acid J J BURNS,* H B BURCH* AND C G KING *Dept of Chemistry, Columbia Univ, New York City*

The gross metabolism of radioactive L-ascorbic acid, labeled with C¹⁴ in the carboxy position, has been studied in normal and scorbutic guinea pigs. The labeled compound was synthesized by addition of radioactive sodium cyanide to L-xylosone. Pure L-ascorbic acid was obtained in 25% yield after purification through ion exchange. Feeding experiments were carried out with normal and scorbutic guinea pigs. The radioactivity appearing in respiratory carbon dioxide during 24 hours was 20-30% of the injected dose. The urine contained 3-6% of total activity, and the feces 0.7%. Calcium oxalate, isolated from the urine, contained 60% of the total urine activity, demonstrating a precursor role of ascorbic acid in oxalate formation. The distribution of radioactivity in organs and tissues was approximately the same as found by chemical analysis for ascorbic acid. There appeared to be no marked differences in tissue incorporation in the normal and scorbutic guinea pig when compared on a unit weight basis. Studies have been made on the incorporation of radiocarbon into the petroleum ether fractions extracted from the spleen and adrenals of scorbutic guinea pigs.

An improved micro-method for sugars using direct colorimetry of ferricyanide GEORGE O BURR AND T TANIMOTO* *Dept of Physiology and Biochemistry, Experiment Station, Hawaiian Sugar Planters' Association, Honolulu, T H*

Clarification of leaf extracts with lead or Somogyi reagent fails to remove a considerable amount of non-sugar reducing material which reacts with cold alkaline ferricyanide. Activated carbon removes this material quantitatively without adsorbing measurable quantities of reducing sugars. At the same time it completely decolorizes the plant extract, making a direct colorimetric reading possible. Based upon the above observations the following micro-method has been developed. To 5 ml of alkaline potassium ferricyanide, containing 0.005 mEq of ferricyanide, is added 2 ml of clarified plant extract which contains not over 180 micrograms of reducing sugars. After heating for 25 minutes in an 80° C water bath the density of the cooled solution is read in a photoelectric colorimeter with a No. 42 filter or in

a spectrophotometer at wave length 420 m/ μ , the absorption maximum for potassium ferricyanide. At this wave length the formed ferrocyanide gives no measurable interference and the decrease in density is proportional to the amount of reducing sugar present. The method is rapid, accurate and sensitive to less than 1 microgram of reducing sugars.

Antibiotic action of the pigments of *Fusarium bos-trycoides* F. A. CAJORI, M. A. HAMILTON,* E. URBANICH* AND T. PURSHOTTAM* *Dept. of Biochemistry, Univ. of Colorado School of Medicine, Denver, Colorado Foundation for Research in Tuberculosis, Colorado Springs*

Culture fluid of *F. bostrycoides* strongly inhibits the growth of the tubercule bacillus, H-37, when tested *in vitro*. The inhibiting action was found to be related to pigment production by the mold. The pigments were extracted from the mold mycelium with hot alcohol and from the highly colored culture fluid with benzene. After freeing the extracts from fat by adsorption on alumina, a crystalline pigment was obtained with antibiotic activity toward the tubercule bacillus similar to the activity of streptomycin when tested by our assay method. This pigment, which has indicator properties, melts at 238°–239° C and is a naphthaquinone, similar to, but not identical with javanicin (ARNSTEIN AND COOK, *J. Chem. Soc.* II 1021, 1947). Experiments bearing on the possible mechanism of the inhibitory action of this material on the growth of the tubercule bacillus will be presented.

Precipitation and separation of 2-hydroxy-3-naphthoic acid hydrazones of conjugated and free ketosteroids BERNARD CAMBER (introduced by R. M. ARCHIBALD) *Hospital of the Rockefeller Inst. for Medical Research, New York City*

Conjugated ketosteroids of unhydrolyzed urine, blood serum, etc. may be precipitated readily at room temperature as hydrazones by addition of 1/10th vol of 0.4% solution of 2-hydroxy-3-naphthoic acid hydrazide (*Nature* 163: 285) in acetic acid. The water washed precipitate from urine has been resolved by paper partition chromatography in a triethylamine–t-butanol–water system into at least 10 components which fluoresce under blue light. Further resolution may be obtained in a second dimensional partition of the colored sulfanilic acid azo derivatives in a water saturated s-butanol system. Quantitation, characterization and further resolution of these precipitates and their azo derivatives is being attempted by column chromatography on alumina and on HIO₄ oxidized starch or cellulose. Transfer of the hydrazide moiety from the steroid to the aldehydic groups of the column involves a new chromatographic principle, 'group exchange'. The hydro-

phobic unconjugated ketosteroids (reference standards, desoxycorticosterone, cortisone, bile acids, urine hydrolysate extracts) dissolved in 0.8% solution of the hydrazide in acetic acid precipitate as hydrazones on addition of 20 vol of 5% methanol in water. A mixture of the hydrazones of steroids known to occur in the β ketonic fraction from acid-hydrolyzed urine (isoandrosterone, dehydroisoandrosterone, allopregnanol-3 β -one-20) has been resolved by paper partition chromatography in an isopropyl ether-triethylamine-water system at 0° C and also in an isopropyl ether-trimethylamine-methanol-water system at room temperature. These methods may facilitate corticosteroid studies in blood and urine and permit removal of ketosteroids from urine without acid hydrolysis. The hydrazide moiety apparently facilitates fractionation and permits visualization and characterization of components.

Methylation of nicotinamide with a soluble enzyme system from rat liver G. L. CANTONI (introduced by S. P. COLOWICK) *Dept. of Biological Chemistry, Univ. of Illinois College of Medicine, Chicago*

The biosynthesis of N¹-methyl-nicotinamide (NMeN) demonstrated earlier in liver slices by Perlzweig and collaborators (*J. Biol. Chem.* 150: 401, 1943) has been studied. It was found that NMeN is formed by an enzyme system obtained from rat liver. The methyl donor is L-methionine. Betaine is active as a methyl donor only in the presence of homocysteine. The reaction is probably endergonic and requires Mg⁺⁺. It was found that the energy of the phosphate bond in ATP or phosphoglyceric acid, the latter used in conjunction with catalytic amounts of ATP, is utilized for the biosynthesis of NMeN. Oxygen is not required. The reaction product was identified as NMeN by a) its ultraviolet absorption spectrum, b) conversion to a fluorescent product with alkali plus methyl-ethyl-ketone, and c) enzymatic oxidation to L-methyl-3-carboxyl-amide-6-pyridone. The enzyme system from rat liver withstands heating at 46° C for 10 minutes and can be fractionated in the cold with ammonium sulfate between 0.4 and 0.50 saturation. A preparation has been obtained which has a specific activity 1.5–2.5 times as great as the crude liver extract. Further work on the purification of the enzyme system and the mechanism of the reaction is in progress. It is suggested that the enzyme responsible for the methylation of nicotinamide by methionine and ATP be called nicotinamide methylkinase.

Oxidation of L-ascorbic acid by o-iodosobenzoic acid WENDELL T. CARANAY* AND LESLIE HELLMAN *Dept. of Physiological Chemistry, Johns*

Hopkins Univ School of Medicine, Baltimore, Md

The oxidation of ascorbic acid by *o*-iodosobenzoic acid proceeds as a second-order reaction in non-buffered aqueous solutions over the pH range from 4-8 with k_2 equal to 1.3 liters mole⁻¹ min⁻¹ at 25° (half-life 13 hours for 0.001 M solutions). The slow rate of the reaction is interpreted on the basis of internal chelation in the molecule of *o*-iodosobenzoic acid since the corresponding *m*- and *p*-iodosobenzoic acids oxidize ascorbic acid practically instantaneously. The acidic component of all buffers tested catalyzed the reaction by combining reversibly with *o*-iodosobenzoic acid to weaken normal internal chelation. An autocatalysis, observed in acetate buffer at pH 4.6 but not in phosphate buffer at pH 7, was traced to *o*-iodobenzoic acid, an end product of the reaction. Dehydroascorbic acid had no effect. A specific catalytic effect of phosphate on the oxidation of ascorbic acid was observed at pH 7. Cupric ion catalyzed the reaction in agreement with observations on the oxidation of ascorbic acid by oxygen. The reaction provides a method for the study of the controlled oxidation of ascorbic acid under various conditions, a problem of considerable interest in view of the undetermined role of the vitamin in oxidation-reduction processes and the mechanism of its action *in vivo*.

Fatty acids as biotin substitutes for *Leuconostoc*

WARNER W. CARLSON, VIRGINIA WHITESIDE-CARLSON AND KATHERINE KOSPETOS (introduced by EMMETT B. CARMICHAEL) *Biochemistry Dept., Med. College of Alabama, Birmingham*.
Previously it was found (CARLSON AND WHITESIDE-CARLSON, *Proc Soc Exper Biol & Med* 71: 416, 1949) that *Leuconostoc* required biotin in glucose and fructose media, but were free of a requirement for this vitamin in sucrose media to the degree that the disaccharide was utilized via the mechanism resulting in dextran synthesis. The ability of fatty acids to substitute for biotin in these carbohydrate media has now been investigated. The fatty acids were used in the form of monoesters of polyoxyethylene sorbitan, compounds known commercially as 'Tweens'. With all strains of *Leuconostoc* employed, Tween 80, the mono-oleate, and Tween 20, the mono-laurate, produced a higher level of growth in sucrose media than was obtained with biotin. In their presence half-maximal to maximal growth was obtained with the various strains in biotin-free glucose and fructose media. Reversal of egg white inhibition by Tween 80 and Tween 20 was observed only with *L. dextranicum* elai, a strain distinguished by giving approximately a quantitative yield of dextran from sucrose. Tween 60, the mono-stearate, and Tween 40, the mono-palmitate, were less

active than the oleate and laurate. Their ability to substitute for biotin in sucrose media paralleled the dextran synthesizing capabilities of the various strains. They could not substitute for biotin in media containing the constituent monosaccharides, and their presence increased the inhibitory effect of egg white. Although most reports stress the ability of unsaturated fatty acids, especially oleic, linoleic and vaccenic acids, to replace biotin, in the case of *Leuconostoc* it appears that lauric acid is also highly effective in the form of Tween 20.

Genesis of C₄ dicarboxylic acids in the tricarboxylic acid cycle S. F. CARSON,* J. W. FOSTER, D. S. ANTHONY* AND E. F. PHARES* *Biology Division, Oak Ridge National Lab., Oak Ridge, Tenn.*

Two recent discoveries concerning biochemical genesis of C₄ dicarboxylic acids require some re-investigation and perhaps some reinterpretations concerning the tricarboxylic acid cycle. First, the recent unequivocal proof of the '2C₂ condensation reaction,' (FOSTER, CARSON, *et al Proc Nat'l Acad Sci* 35: 663, 1949), second, the finding that metabolic CO₂ can become incorporated into carboxyl groups of preformed C₄ dicarboxylic acids, but which were synthesized by the 2C₂ condensation reaction (FOSTER, CARSON *et al Proc Nat'l Acad Sci*, in press). Krebs type malonate inhibition experiments were conducted with C¹⁴H₂COCOOH and C¹³O₂. Malate, succinate, lactate and α-ketoglutarate were isolated, purified and completely degraded, specific activities were determined for both C¹³ and C¹⁴. The results indicate that the 2C₂ condensation reaction cannot be excluded from having taken part in the synthesis of the C₄ dicarboxylic acids. It is also indicated that one may have to re-examine the quantitative significance of the role of CO₂ in the actual synthesis of C₄ dicarboxylic acids, versus the amount of labeled CO₂ which merely enters by simple reversible exchange with already existing C₄ acids. Finally, it should be pointed out that in all the malonate experiments, the controls formed as much succinate (frequently more) than the treatment containing substrate. As far as we are aware, very few, if any, isotope experiments on the tricarboxylic acid cycle have been conducted with controls. Our controls yielded malate containing as much C¹³ in carboxyl (from C¹³O₂) as the pyruvate experiments.

Structure of cerebrosides HERBERT E. CARTER, FRED L. GREENWOOD* AND CHARLES G. HUMISTON* *Division of Biochemistry, Noyes Lab of Chemistry, Urbana, Ill.*

In previous work we have shown that triacetyl-sphingosine yields acetic acid on catalytic reduction as a result of cleavage of the allylic acetox-

group The product has now been isolated and shown to be diacetylsphingine Oxidation of N-benzoylsphingine gave an optically active N-benzoylaminostearic acid which, on racemization through the azlactone, was converted into the known DL-benzoyl- α -aminostearic acid These results furnish final confirmation for the structure of sphingosine The optically active benzoyl- α -aminostearic acid is tentatively assigned the D-configuration on the basis of studies of optical rotation of acylated amino acids in various solvents Catalytic reduction of hexaacetylphrenosin yielded acetic acid but no reducing sugar Hydrolysis of the product gave sphingine The structure of cerebrosides will be discussed in the light of these data

Reaction of ferrocytochrome-c with peroxidases and peroxides BRITTON CHANCE (introduced by J M BUCHANAN) *Johnson Research Foundation, Univ of Pennsylvania, Philadelphia*

The reaction of ferrocytochrome-c with the peroxide complexes of the 4 purified peroxidases (horse-radish (HRP), verdo (VPO), lacto (LPO), and cytochrome-c (CCP) peroxidase) has been found to be very rapid, of roughly the same or greater speed than the combination of these peroxidases with other electron donors or with hydrogen peroxide Since the latter reaction has a very low energy of activation (< 2000 cal based on experiments on HRP and catalase), it is suggested that the reaction of the large cytochrome-c molecule occurs at a larger active center than the iron-porphyrin group of the peroxidases A characteristic of the kinetics of the reactions catalysed by LPO, VPO, and HRP is a saturation effect which may be caused by the formation of a peroxidase-peroxide-cytochrome-c complex of a dissociation constant of about 1×10^{-6} M Although CCP has the highest activity (k_4 for the reaction of CCP H_2O_2 with cytochrome-c is about $10^8 M^{-1} \times sec^{-1}$ and k_4 for the others is $0.6 - 1 \times 10^7 M^{-1} \times sec^{-1}$ at pH = 4.7) the activity of the other peroxidases is considerable and, for HRP and VPO, is comparable to rough estimates of the turnover of cytochrome-c in plant cells and leucocytes The activity of the enzymes is fragile, HRP and CCP are readily inactivated by the turnover of several separate additions of ferrocytochrome-c In the case of HRP, the activity is restored by the addition of p phenylene diamine

Fractionation of coenzyme A-dependent acetyl transfer systems T C CHOU,* G D NOVELLI,* E R STADTMAN* AND FRITZ LIPMANN *Biochemical Research Lab, Massachusetts General Hospital and Dept of Biological Chemistry, Harvard Med School, Boston*

Pigeon liver extract was fractionated into acetyl donor and various acetyl acceptor fractions by use

of acetone fractionation in the cold combined with protamine precipitation At pH 8.2, 40% acetone precipitates the acetyl donor fraction (ATP-acetate reaction) together with the acetoacetate- and citrate-synthesis acceptor systems The sulfanilamide acceptor enzyme remains dissolved and may be precipitated by increasing the acetone concentration to 60% The 40% acetone precipitate was dissolved and treated further with protamine Therewith, the acetoacetate acceptor enzyme was precipitated and separated from the citrate system which remained in solution As donor system with the acetyl acceptor fractions from liver extract, a microbial enzyme (*Clostridium kluyveri* or *butylicum*, *E coli*) may be used which brings synthetic acetyl phosphate into reaction With acetyl phosphate as the acetyl donor in such mixed enzyme systems, it could be shown that in the condensation with oxalacetate to citrate, the acetyl-bound phosphate is split off, and free citrate is formed It furthermore appears that 2 acetyl phosphate molecules enter acetoacetate synthesis This is shown 1) by a 2:1 ratio of acetyl phosphate disappearance to acetoacetate formation and 2) by use of carboxyl-labelled acetyl phosphate With the latter acetoacetate was obtained which was labelled nearly equally in the carbonyl and carboxyl positions

Succinic dehydrogenase—cytochrome C link in heart muscle succinoxidase HAROLD W CLARK (introduced by ELMER STOTZ) *Dept of Biochemistry, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*

Several claims have been made for an 'S-C factor,' that is, a factor necessary for reduction of cytochrome c by succinic dehydrogenase and succinate These claims have been attributed, however, to unspecific effects in the complex association of factors in the particulate matter of the succinoxidase system (KEILIN, D AND E F HARTREE, *Biochem J* 44 205 1949) By ammonium sulfate fractionation of a pig heart extract in the presence of 2% cholate, a succinic dehydrogenase preparation (i.e., one which with succinate reduces O-chloro,2,6-dichlorophenol indophenol) is obtained which does not reduce cytochrome c in the presence of succinate and KCN Neither dialysis of the preparation, nor addition of inert proteins or calcium phosphate gel established reduction of cytochrome c Addition of an ammonium sulfate fraction obtained with lower cholate concentration caused a reduction of cytochrome c, and the rate of reduction served as an assay for the 'S-C factor' activity of the added fraction Cholate itself did not affect the assay in the concentrations encountered Various other treatments caused great variations in the ratio of 'S-C' succinic dehydrogenase, indicating the sepa-

rate nature of the 2 factors, although an 'S-C' preparation has not yet been obtained entirely free of the dehydrogenase. A combination of ammonium sulfate fractionations and $\text{Ca}_3(\text{PO}_4)_2$ adsorption has thus far resulted in an 'S-C' preparation approximately 40-fold purified over the original heart muscle extract.

Effect of cortisone on protein metabolism in the rat as studied with isotopic glycine I. CLARK (introduced by R. H. SILBER) *Merck Inst for Therapeutic Research, Rahway, N. J.*

Normal and adrenalectomized rats weighing about 220 gm each received 3 mg of cortisone acetate subcutaneously daily for 5 days. They were maintained on a constant food intake and received 1.0% sodium chloride in their drinking water. On the fourth day they received a tracer dose of glycine containing 32% N^{15} . Urinary urea ammonia, total nitrogen and N^{15} were determined in the usual manner. It was found that cortisone markedly increased urinary nitrogen excretion. Its greatest influence was on the adrenalectomized animals. Since the excretion of the isotope reflects the amount of nitrogen being used for protein synthesis, the amount of protein synthesized can readily be calculated. In the animals receiving cortisone there was a decrease in protein synthesis as compared to the control animals. The significance of these findings and the effect of cortisone on the size of the metabolic pool and on protein catabolism will be discussed.

Method for the estimation of 2-keto-hexonic acids

SEYMOUR S. COHEN AND MARY C. LANNING * *Dept. of Pediatrics, Children's Hospital of Philadelphia and the Dept. of Physiological Chemistry, Univ. of Pennsylvania School of Medicine, Philadelphia*

Various 2-keto acids condense with o-phenylene diamine to form quinoxalines. The spectra of the compounds formed by this reagent with pyruvic acid and with 2-ketogluconic acid, as an example, are quite similar, showing a marked absorption maximum at 330 $\text{m}\mu$. The formation of these compounds as a function of pH, temperature, concentration of reagent and duration of heating has been examined. Conditions have been established for the specific estimation of 2-keto-hexonic acids in microgram quantities, unaffected by the presence of relatively large amounts of gluconic and 5-ketogluconic acids. Dehydro-ascorbic acid interferes markedly in this estimation. The selected conditions minimize the slight interference by ribose. Quinoxaline formation enables the ready detection of 2-keto-hexonic acids, otherwise difficultly detectable, on paper chromatograms. The application of this reaction to the study of the enzymatic degradation of 6-phosphogluconic acid will be discussed.

Studies on the synthesis of creatine in homogenates of the liver STANLEY COHEN (introduced by F. CAJORI) *Depts. of Pediatrics and Biochemistry, Univ. of Colorado School of Medicine, Denver*

As part of a study of the synthesis of creatine from amino acids by homogenates of the liver of the adult and embryonic stages of development of various species, a source of error in the analytical procedure has been found. The 'creatine' synthesized by homogenates of beef liver from guanidoacetic acid and DL-methionine was found to be almost entirely an artefact due to the formation of α -keto- γ -methiolbutyric acid from D-methionine, which gives a marked color with alkaline picrate solutions. This interference may be avoided by the use of L-methionine and adsorption of the creatine formed on Lloyd's reagent prior to the determination. The survey of the ability of homogenates of the liver of various vertebrate animals to synthesize creatine from L-methionine and guanidoacetic acid has indicated that the liver of the guinea pig is the most efficient in this respect. The reaction requires Mg^{++} and is inhibited by Ca^{++} . The details of these experiments are presented.

Separation of adenosine polyphosphates by ion-exchange and paper chromatography WALDO E. COHN AND CHARLES E. CARTER * *Biology Division, Oak Ridge Natl. Lab., Oak Ridge, Tenn.*

Methods for the separation of mononucleotides by ion-exchange and paper chromatography, previously described, have been applied to the separation of AMP, ADP and ATP from their mixtures. A quantitative isolation of each of these three compounds from the others, as well as from adenine and adenosine if present, is achieved by successive elution from a strong-base anion-exchange column with 0.01 N-NH₄Cl (bases and ribosides), 0.01 N-HCl (AMP plus monophosphorylated nucleotides, if present), 0.01 N-HCl + 0.02 N NaCl (ADP) and 0.01 N-HCl + 0.2 N NaCl (ATP). Quantities of between 0.1 and 10 mg can be handled on a 1 cm \times 1 cm² column at flow rates of up to 3 ml/cm² min, using 100 ml volumes of these reagents after absorption of the mixture from ammoniacal solution. Paper chromatograms are developed with an isoamyl alcohol-disodium phosphate mixture and the components are detected by fluorescence as previously reported. Analyses of various commercial preparations of ADP and ATP show varying amounts of the compounds. The ion-exchange separation, accomplished within 3 hours, is suitable both for analysis and the preparation of pure material.

Absorption and distribution of C^{14} labeled fatty acids in the rat JOHN G. CONIGLIO, * CARL L. ANDERSON * AND C. S. ROBINSON *Dept. of Bio-*

chemistry, Vanderbilt Univ Med School, Nashville, Tenn

The deposition of fatty acids in the liver and depot fat of rats was studied 5 and 7 hours after feeding C^{14} -labeled fatty acids obtained by biosynthesis. Five young fasted rats were fed between 83 and 275 mg of the labeled fatty acids and killed 5 or 7 hours after feeding. The highest concentration of radioactivity was found in the liver, but a significant percentage was found in the mesentery lipids. No differences were observed in the distribution of the adsorbed C^{14} in the lipids of these tissues between the 5- and 7-hour experiments. In the liver the specific activity of the triglyceride fatty acids was always higher than that of the phospholipid fatty acids. The ratio between the two was constant and averaged 2.23. In 3 experiments the fatty acids associated with the esterified cholesterol had a higher specific activity than those of the neutral fat fraction. The 'free fatty acids' of the liver had a specific activity identical with that of the phospholipid fatty acids suggesting an origin in the autolytic decomposition of the phospholipids of the excised liver. In the mesentery the major part of the C^{14} of the total fatty acids was associated with the neutral fat fraction, but in the two experiments the specific activity of the phospholipid fatty acids was higher. The free fatty acids of the mesentery had a higher specific activity than any other fraction indicating a deposition of absorbed fatty acids or soaps as such. In 5 to 7 hours an average of 80% of the ingested fatty acids was absorbed and a small fraction oxidized.

Oxidation of triphosphopyridine nucleotide by plant enzymes ERIC E. CONN* AND BIRGIT YENNESLAND *Dept of Biochemistry, Univ of Chicago, Chicago, Ill*

Fractionation of the soluble proteins of wheat germ has led to the observation that this plant source contains a number of enzymes which act upon triphosphopyridine nucleotide (TPN) as a substrate. One protein fraction causes a destruction of the nucleotide. It hydrolyzes one phosphate group very rapidly from oxidized TPN but not from reduced TPN. Pyrophosphatase activity is also present. A separate protein fraction catalyzes the aerobic oxidation of reduced TPN. At least two different proteins are necessary for the oxidation. The reaction is inhibited by cyanide and by catalase. Accumulation of hydrogen peroxide cannot be demonstrated. Cytochrome c is not a component of the enzyme system. All active preparations contain high peroxidase and cytochrome peroxidase activity. Purified horseradish peroxidase alone cannot cause the oxidation of reduced TPN, either in the presence or the absence of added hydrogen peroxide. When horse-

radish peroxidase is added to the wheat germ enzyme, however, a stimulation of the rate of oxidation of reduced TPN is observed. Reduced diphosphopyridine nucleotide is oxidized about one-fourth as rapidly as reduced TPN. The oxidation of both substances appears to occur by a mechanism different in nature from that previously postulated for hydrogen transport from pyridine nucleotides to molecular oxygen.

Metabolic fate of the isopropyl group of leucine

MINOR J. COON (introduced by D. WRIGHT WILSON) *Dept of Physiological Chemistry, Univ of Pennsylvania School of Medicine, Philadelphia*

In liver tissue, the α and β carbons of leucine split off as a two-carbon unit which is capable of condensing to form acetoacetate. Experiments have recently been carried out to determine whether the isopropyl group of the amino acid also contributes to ketone body formation. Liver slices from fasted rats were incubated at 38° in a Ringer-phosphate buffer solution containing γ - C^{14} -leucine. The acetoacetate which was produced was degraded independently by permanganate and by Denigès' reagent, and it was found to be labeled chiefly in the carbonyl carbon. In similar experiments where β - C^{14} -isovaleric acid was the substrate, the resulting acetoacetate and β -hydroxybutyrate were each degraded by standard procedures to yield acetone and carbon dioxide. From the radioactivity of the products, it was calculated that in each acid the amount of C^{14} in the β carbon was approximately 20 times that in the carboxyl carbon. It is proposed that the isopropyl group of leucine (or isovalerate) yields a two-carbon intermediate which acts almost exclusively as an acetylating agent in forming acetoacetate. A similar hypothesis has been used by Crandall, Brady and Gurin in order to explain the behavior of the terminal fragment arising from octanoic acid.

Effect of niacin and tryptophane in counteracting toxicity of crystalline borrelidin for rats J. M. COOPERMAN,* S. H. RUBIN AND B. TABENKIN* *Depts of Nutrition and Microbiology, Hoffmann-La Roche Inc., Nutley, N. J.*

The production of pellagra like signs in animals fed toxic materials has been reported by several investigators. The role of corn in the production of niacin deficiency in the rat has been described by Krehl *et al.* Berger, Jampolsky and Goldberg described the isolation from broth of a *Streptomyces* species of a rather toxic crystalline antibiotic, borrelidin, a borrelidin-like material was also found in concentrated corn steep liquor. Experiments were designed to test the effectiveness of niacin and tryptophane in overcoming the toxicity of borrelidin in the rat. The basal ration contained 20% casein, 71% sucrose, 4% salts IV,

3% cod liver oil and 2% corn oil. Vitamins were supplied in large excess (5-50 times known minimum requirements). Rats were given 10 mcg borrelidin per day orally and their growth compared to a control group receiving no borrelidin and a group of rats receiving 1 mg niacin in addition to 10 mcg borrelidin per day. At the end of 4 weeks, the average gain per week in grams was control group 31, borrelidin group 11, borrelidin and niacin 22. In another experiment designed to test the effect of tryptophane in overcoming the toxicity, the borrelidin, niacin and tryptophane supplements were added directly to the basal ration. The average gain per week in grams at the end of 4 weeks was control group 35, group receiving 1 mg borrelidin/kg of ration 14, group receiving 1 mg borrelidin and 500 mg niacin/kg of ration 20, and group receiving 1 mg borrelidin and 5 grams DL-tryptophane/kg of ration 18.

Amylo-1,6-glucosidase GERTY T. CORI AND JOSEPH LARNER* *Dept of Biological Chemistry, Washington Univ School of Medicine, St Louis, Mo*

Phosphorolysis of branched polysaccharides by plant or animal phosphorylase stops when the enzyme approaches a branch point where one glucose residue is connected instead of with two, with three others, one of which is in 1,6-linkage. Thus only 40% of glycogen undergoes phosphorolysis and a limit dextrin is left. When a protein fraction, obtained from muscle, is added to phosphorylase, the entire glycogen molecule is digested. This fraction contains an enzyme for which the name amylo-1,6-glucosidase is proposed. A solution containing polysaccharide, phosphate, muscle phosphorylase and glucosidase was incubated (10 min) until the glycogen had disappeared. Protein, phosphorylated sugar and salt were then removed from the solution and paper chromatography for reducing sugars carried out on it. A single spot was obtained which was identified as glucose. Quantitative determinations of glucose and phosphorylated sugar revealed that the ratio, glucose/phosphorylated sugar, varied in proportion with the degree of branching of the polysaccharide used. Lowest values were obtained with amylopectins, glycogen was intermediate and limit dextrin gave the highest values. It is concluded that the glucosidase acts by hydrolyzing the 1,6-linkage in amylo polysaccharides once this linkage has been exposed by preceding phosphorylase action. Six glucose residues are left distal to each branch point after exhaustive phosphorylase action. In order to explain the formation of glucose one must assume that these residues are unevenly distributed, one branch having one and the other 5 glucose residues. The present findings furnish an explanation for the

observation that small amounts of glucose are formed in muscle during rapid breakdown of glycogen.

Subacute toxicity of radioactive phosphorus as related to the composition of the diet W. E. CORNATZER,* GEORGE T. HARRELL, JR.,* DAVID CAYER* AND CAMILLO ARTOM *Depts of Biochemistry and of Internal Medicine, Bowman Gray School of Medicine, Winston-Salem, N. C.*

Mice were maintained on various diets for 5 days before and 21 days after the injection of a single dose of P^{32} as Na_2HPO_4 . The percentage survival, the time at which 50% deaths occurred and the average survival time were recorded. Neither the fatty infiltration of the liver (produced by a low protein, high fat diet or by poisoning with CCl_4), nor its prevention by supplementing the diet with choline affected appreciably the toxicity. Susceptibility to radiation injury by P^{32} was lowest in mice on a 10% casein, 5% fat diet, and increased distinctly when the protein, or the fat level, or both, were increased. It is suggested that these findings may be related to the specific dynamic action of dietary protein and fat. Increasing the phosphate content of the diet seemed to protect the animals, to a certain extent, presumably as the result of an increased exchange of the P^{32} deposited in the bones.

Sulfur metabolism of *E. coli* D. B. COWIE AND M. SANDS (introduced by HELEN M. DYER) *Carnegie Inst of Washington, Dept of Terrestrial Magnetism, Washington, D. C.*

The utilization of sulfur by *E. coli* has been investigated through studies of the multiplication of cells, uptake of S^{35} by growing cells, and the biosynthesis of compounds containing S^{35} . The growth of cultures of *E. coli* is found to depend upon sulfur concentration for low levels of sulfur incorporated into media as sulfate, sulfite or sulfide, while for higher concentrations growth is independent of sulfate level and is inhibited by sulfite and sulfide. When 'water-space' sulfur is accounted for, the uptake of S^{35} may be quantitatively described by a Langmuir adsorption isotherm. Furthermore, it is demonstrated that, in the presence of adequate amounts of sulfur, S^{35} uptake is directly proportional to the number of new cells formed in a growing culture, indicating a sulfur composition of 3 to 4 mg sulfur/ml of bacterial cells. Methionine containing S^{35} is identified as one of the products of sulfur metabolism while the presence of other S^{35} compounds is indicated.

Fixation of carbon dioxide by mammalian tissues and its relation to carbohydrate metabolism ROBERT K. CRANE* AND ERIC G. BALL *Dept of Biological Chemistry, Harvard Med School, Boston, Mass.*

Studies on CO_2 fixation were carried out by incubating tissue with pyruvate in the presence of C^{14}O_2 . The residual pyruvate at the end of the experiment was isolated and purified as the 2,4-dinitrophenylhydrazone and the radioactivity of this derivative was assayed. Intact ox retina and rat diaphragm show high rates of CO_2 fixation. In the case of ox retina, the formation of radioactive pyruvate would appear to involve the following reversible reactions

The energy requirement is apparently met by coupling of reaction (1) with reaction (3)

Evidence for this is furnished by the following observations: 1) Anaerobically the rate of incorporation progressively decreases with time and is virtually zero at the end of two hours. The glycogen content of ox retina is found to average only $0.92 \mu\text{g}/\text{mg}$ wet weight. The addition of glucose anaerobically maintains the rate constant for at least 4 hours and at a level equal to the aerobic rate. 2) Neither arsenate which inhibits the production of ATP by the triosephosphate dehydrogenase reaction nor fluoride which inhibits the enolase reaction has any large inhibitory effect on anaerobic CO_2 incorporation. 3) Iodoacetate in concentrations sufficient to inhibit glycolysis by 95% actually increases the anaerobic rate by 75%.

Influence of dietary protein FRANK A. CSONKA

Bureau of Human Nutrition and Home Economics, Agricultural Research Admin., USDA, Washington, D. C.

The nitrogen, methionine and cystine contents of the hen egg will be discussed in reference to their distribution in the egg white and yolk as affected by 1) aging of the hen and 2) by the feed. Eggs of pullets in their first-year laying season were analysed. As pullets, fed a low protein diet, aged, nitrogen decreased in the egg white and increased in the yolk, with pullets fed a high protein diet the nitrogen increased in both. The quantities of sulfur amino acids in the white and yolk of their eggs generally paralleled the changes in nitrogen values. However, the cystine/methionine ratio in the egg white decreases with aging of the pullet regardless of the diets employed here. An increased ratio in the yolk resulting from aging was found to be statistically significant only during the low protein dietary regimen. This increased ratio in the yolk, characteristic for eggs laid by older pullets, may be duplicated in younger pullets' eggs by feeding them a high protein diet. Enzymatically digested casein in the hen's feed increased the cystine and methionine content of the

egg to the same extent as did casein. Previously we reported that free methionine supplementation to the hen's feed did not alter the egg sulfur amino acid content. The experiment with predigested casein indicates the importance in protein synthesis of the availability and simultaneous absorption of all the amino acids required.

Effect of high pressures on activity of proteinases

A. LAURENCE CURL* AND EUGENE F. JANSEN
Enzyme Research Division, Bureau of Agricultural and Industrial Chemistry, Agricultural Research Admin., USDA, Albany, Calif.

The effect of high pressures on the activation of chymotrypsinogen by trypsin has been studied in connection with a general investigation of the effect of high pressures on enzymes, in particular crystalline proteinases. Chymotrypsinogen was not activated by pressure in the absence of trypsin. No significant change in the extent of activation by trypsin was found under pressures up to 700 bars. About 10% less activation than in an unpressed system was observed under a pressure of 1000 bars. The inhibition of the reaction increased with increase in pressure and practically no reaction occurred at 3000 bars. Up to this pressure the activation proceeded after release of the pressure at practically the same rate as initially in the control. Following release of systems at higher pressures than this, progressively less activity was obtained, until after pressing at 5700 bars no active enzyme was formed. The effect on the mixture of chymotrypsinogen and trypsin was much greater than on either protein alone.

Proteins of cellular nuclei R. DUNCAN DALLAM, WILLIAM R. KIRKHAM, TUNG-YUE WANG, LLOYD E. THOMAS AND DENNIS T. MAYER (introduced by SAMUEL BRODY) *Depts. of Biochemistry and Agricultural Chemistry, Univ. of Missouri, Columbia*

It was previously reported that boar spermatozoa contain alkali-soluble protein fractions which are precipitable by acid. Mechanical separation of the heads of these cells from the tails and midpieces has shown that all such proteins are present in the heads. By extracting the cells first with 0.1 N sodium hydroxide there is obtained only one protein fraction which precipitates with acetic acid at about pH 6. Subsequent extraction with 1.0 N sodium hydroxide yields a small fraction precipitating with acetic acid at about pH 10. Neither of these fractions contains appreciable quantities of nucleic acid. The residue is composed entirely of 'ghost' heads which are rich in arginine and nucleic acid. Rat liver nuclei isolated by the Dounce procedure and calf thymus 'chromosomes' isolated by the method of Mirsky and Ris contain an alkali-soluble protein fraction which precipitates at about pH 6. After extraction

of the nucleohistone and the 'pH 6 fraction' from the liver nuclei or thymus 'chromosomes' only a small residue remains, the chemical nature of which remains to be determined

Effect of exclusion of oxygen from the hydrolysis by Blau's method upon detection of thyroxine from thyroglobulin MARSHALL E. DEUTSCH (introduced by ISIDOR GREENWALD) *Dept of Chemistry, New York Univ College of Medicine, New York City*

Beef and sheep thyroglobulin containing, respectively, 0.821 and 0.784% iodine were hydrolyzed by Blau's method (*J Biol Chem* 110:351, 1935) with the exception that the hydrolyses were performed in tubes which had been sealed immediately after the air in them had been displaced by nitrogen. Under these conditions, the author could not identify thyroxine in the 'thyroxine' fraction. When the hydrolyses were performed in sealed tubes in the presence of added thyroxine equivalent to 0.237% by weight (sheep thyroglobulin) or under a reflux condenser (beef thyroglobulin), the presence of thyroxine was demonstrable. In hydrolysates of commercial egg albumin, 0.090 but not 0.045% thyroxine (added before hydrolysis) was easily detectable. The method used was to concentrate and chromatograph the material in the butanol extracts. Thyroxine and diiodotyrosine were identified by the R_f of substances giving the following reactions: a) quenching of the fluorescence of the paper under ultra-violet light, b) the colors appearing upon spraying with ninhydrin a longitudinal strip cut from the paper, c) the colors appearing on a strip sprayed with Millon's reagent, d) the colors appearing upon spraying with 1) acidulated starch-KIO₃ solution, 2) NaNO₂ solution and 3) NH₃ solution in that order.

Preliminary characterization of two biotin-containing fractions in beef liver DANIEL F. DICKEL,* A. E. AXELROD* AND KLAUS HOFMANN *Dept of Chemistry, Univ of Pittsburgh, Pittsburgh, Pa*

A large fraction of the biotin in animal tissues has been assumed to be firmly bound to the tissues and treatments known to destroy proteins have been used routinely to liberate the vitamin from these materials for microbiological assay. The present study was directed towards the isolation and characterization of biotin protein complexes from animal tissues, since it seems likely that they represent the enzymatically active forms of biotin. Beef liver was dehydrated with acetone and the resulting acetone liver powder extracted under mild conditions. The resulting extracts were assayed by the yeast growth method for their biotin content before and after hydrolysis with acid. It was found that beef liver contains at least

two distinct biotin-containing fractions. One of these is extractable with a buffer at pH 3 and loses its biotin activity on dialysis; the other is soluble in dilute sodium hydroxide and is not affected by dialysis. The pH 3 soluble substance has practically the same biotin activity before and after acid hydrolysis, in contrast to the alkali soluble compound which has very little activity initially but becomes highly active following hydrolysis with sulfuric acid. In accordance with the accepted term *flavoprotein* we propose that the term *biotoprotein* be applied to biotin-containing proteins as they occur in tissues. It is assumed that the sodium hydroxide soluble material represents such a *biotoprotein*. The possible enzymatic functions of this material are under investigation.

Studies on aconitase SHERMAN R. DICKMAN AND A. A. CLOUTIER (introduced by EMIL L. SMITH) *Dept of Biological Chemistry, University of Utah College of Medicine, Salt Lake City*

Aqueous extracts of horse heart exhibiting aconitase activity have been prepared almost free of the red pigment or pigments which usually accompany the enzyme. The pigmented material is extracted first by blending ground, frozen heart with dilute ethyl alcohol, followed by centrifugation. The supernatant solution is highly colored and contains little aconitase activity. The residue is immediately blended with water or phosphate buffer and chloroform and the emulsion centrifuged. The clear, pale pink supernatant solution exhibits appreciable aconitase activity. This activity can be augmented considerably after overnight incubation with Fe⁺⁺ and cysteine. Additional pigment can be subsequently removed from such solutions by fractionation with ammonium sulfate. The activating and stabilizing effect of ferrous ion (DICKMAN AND CLOUTIER, *Arch Biochem* In press) on crude aconitase preparations has been extended to the ammonium sulfate fractions. Many solutions which exhibit very low aconitase activity have been found to develop appreciable activity after incubation with ferrous ammonium sulfate. This activation occurs relatively slowly and often the solution does not exhibit maximum aconitase activity until after one to two days' incubation.

Neutral mucopolysaccharides from various animal tissues ZACHARIAS DISCHE AND MARTHA OSNOS* *Dept of Biochemistry, Columbia Univ College of Physicians and Surgeons, New York City*

Fractions of neutral mucopolysaccharides were prepared from brain, kidney, muscle, heart and pancreas of rat, mouse kidney, sarcoma 180 and human serum. Nucleic acids were removed from homogenized tissues by 4S^b extraction with 5% TCA at room temperature, lipids by ethanol-

ether extraction The residue, dissolved in $\frac{N}{2}$ NaOH, was precipitated with 90% ethanol, the precipitate hydrolyzed in 5 N KOH for 3^h at 100°. One polysaccharide fraction was obtained by precipitating the hydrolysate with 2, a second with 9, volumes of ethanol (fraction II) True sugars in fraction II were identified and quantitatively determined by the spectrophotometric absorption of products of their reactions with cysteine in H₂SO₄, by the characteristic speed of destruction of these products by water (*J Biol Chem* 175 595, 1948, 181 379, 1949, *Arch of Biochem* 22 169, 1949), and by fermentation Hexosamine was determined by a new reaction with indole and HCl Fraction II from 10 g brain, kidney and serum contained, 3,5 5 mg of carbohydrate, consisting of hexosamine, D-mannose, galactose and methylpentose Approximate mannose galactose ratios for brain, kidney, serum were 7,2, 1 respectively Methylpentose galactose varied in the same range as in purified blood group substances from various sources The amount of hexosamine was roughly half of the sum of mannose plus galactose Smaller amounts of the same sugars were found in fraction II of the other tissues These findings suggest the presence in most animal tissues of protein bound polysaccharides of the type found in serum and blood group substances

Effect of vitamin B₁₂ on the reduction of S-S compounds in vitro JACOB W DUBNOFF *California Inst of Technology, Pasadena*

Addition of vitamin B₁₂ concentrates to liver slices and homogenates increases the reduction of S-S compounds by preformed and added hydrogen donors The specificity of hydrogen donors and the relation of this effect to methionine synthesis from homocystine will be discussed

Synthesis of peptides containing amino acid antagonists FLOYD W DUNN AND KARL DITTMER (introduced by V DU VIGNEAUD) *Depts of Chemistry of Univ of Colorado, Boulder, and Florida State Univ, Tallahassee*

The following peptides have been prepared by the Bergmann carbobenzoxy method carbobenzoxyglycyl- β -2-thienylalanine (I), carbobenzoxyglycyl- β -3-thienylalanine (II), carbobenzoxyglycyl- β -2-thienylalanylglycine (III), carbobenzoxyglycyl-*para*-methylphenylalanine (IV), carbobenzoxyglycyl- β -1-naphthylalanine (V), and carbobenzoxyglycyl- β -2-naphthylalanine (VI) The sulfur-containing carbobenzoxy peptides were reduced with phosphonium iodide to obtain glycyl- β -2-thienylalanine (VII), glycyl- β 3-thienylalanine (VIII), and β -2-thienylalanylglycine (IX), glycyl-*para*-methylphenylalanine (X) was prepared by the usual catalytic method of hydrogenation of IV

Compounds VII, VIII and IX inhibit the growth of *Escherichia coli*, 50% inhibition being produced by 2 2 γ , 1 15 γ , and 1 25 γ , respectively, this compares with 50% inhibition obtained by 1 05 γ of free β -2-thienylalanine or by 0 6 γ of β -3-thienylalanine The growth inhibition caused by the peptides containing amino acid antagonists can be reversed by phenylalanine or *para*-methylphenylalanine, 50% reversals being obtained with 1 4 γ and 1 6 γ , respectively β -2-Thienylalanine inhibition can be reversed by phenylalanylglycine, glycylphenylalanine or glycyl-*para*-methylphenylalanine, with 50% reversals occurring at the following levels, respectively 1 9 γ , 2 3 γ and 5 4 γ When yeast is used as the test organism the peptides are much less effective than the corresponding free amino acids either as inhibitors or as reversers of inhibition The enzyme carboxypeptidase splits compounds I, II, IV, V and VI

Two-dimensional ionophoresis and electrophoresis E L DURRUM (introduced by RAY G DAGGS) *Med Dept Field Research Lab, Fort Knox, Ky*

A technique for the separation of amino acids, peptides and proteins wherein an electrical potential is applied across the ends of filter paper strips saturated with electrolyte solutions, to which have been applied at narrowly circumscribed intermediate areas the mixtures to be separated, has been extended in a manner analogous to two-dimensional paper chromatography The method appears to be widely applicable and to be much more rapid than conventional paper chromatography The technique will be described together with examples of types of separations attainable

Microbiological response to amino acid derivatives CHARLES H EADES, JR (introduced by T P NASH, JR) *Dept of Chemistry, School of Biological Sciences, Univ of Tennessee, Memphis*

The acetyl, chloroacetyl, and acetyldehydro derivatives and the keto analogs of leucine, phenylalanine, tryptophan, and valine were investigated with regard to their growth effects on 3 commonly used microorganisms, *Lactobacillus arabinosus*, *Lactobacillus casei*, and *Leuconostoc mesenteroides* The results indicate that the acetyl and chloroacetyl derivatives of DL-leucine were effective in replacing the amino acid for the growth of *L arabinosus* DL-acetyl and DL-chloroacetyl tryptophan were used in place of DL-tryptophan by *L casei* The keto analogs of leucine and valine were used by both *L arabinosus* and *L casei* to the same extent as the DL amino acids were used The acetyldehydro derivatives of the amino acids investigated were all ineffectual in supporting the

Comparison of lymphoid tumor and muscle electrolyte composition in patients treated with ACTH and cortisone acetate LEONARD P. ELIEL, OLOF H. PEARSON, BERNICE KATZ AND FRANCES W. KRAINTZ (introduced by KONRAD DOBRINER) *Division of Clinical Investigation, Sloan Kettering Inst., New York City*

Marked, progressive decrease in the size of enlarged lymph nodes and of enlarged spleens has been demonstrated in patients with chronic lymphatic leukemia and follicular lymphosarcoma who were given ACTH or cortisone acetate (*Cancer* 2:943, 1949). During treatment these patients exhibited phosphorus excretions (corrected for calcium) which were approximately twice that expected from the nitrogen loss, based on the usually accepted P/N ratio in normal protoplasm. Analyses of dry, blood-free, fat-free tissues from 4 of these patients revealed phosphorus concentrations which, per unit of nitrogen, were 3 times higher in tumors and lymphocytes than in muscle. It is believed, therefore, that the high phosphorus excretion indicates tumor destruction resulting from ACTH and cortisone administration. The ratio of P to N excreted lies midway between the ratio found in tumor tissue and that in muscle, providing evidence that both normal tissue and tumor were being destroyed. No significant changes in tissue P or N concentration were evident after therapy. The $K(mEq)/N(gm)$ ratio in untreated tumor tissue was 4.0-4.4, in muscle 2.2-3.0. Two patients demonstrated slight falls (15, 25.5 mEq/kg) in muscle potassium and large falls (194.4, 79.7 mEq/kg) in tumor potassium under therapy. The K/N ratios in the tumors fell to 3.0 and 3.7. A third patient showed no change. The significance of these findings with respect to growth and destruction of tumor tissue will be discussed.

Inhibitory effects of 2,6-diaminopurine on growth of *Lactobacillus casei* GERTRUDE B. ELION* AND GEORGE H. HITCHES *Wellcome Research Labs., Tuckahoe, N. Y.*

2,6-Diaminopurine strongly inhibits the growth of *Lactobacillus casei* in a medium containing folic acid and no purines. This antagonism of folic acid is not competitive and is only partially reversed by increasing the concentration of folic acid. At low levels of diaminopurine, reversal of the inhibition may be obtained with adenine, guanine, xanthine or hypoxanthine, whereas at high levels of the inhibitor, only adenine is effective, reversal by adenine takes place over a wide range of concentration of the inhibitor. When *Lactobacillus casei* is grown in a medium containing thymine and a purine, in place of the folic acid medium, diaminopurine appears to be less inhibitory. However, this may be due to the fact that inhibition can be

demonstrated only at suboptimal levels of adenine where growth is small. Nevertheless, the relatively greater effectiveness of adenine as a reversing agent as compared with guanine can be shown also with the thymine grown organism.

Factors affecting acetylcholine (ACh) found in rat brain K. A. C. ELLIOTT AND NORA HENDERSON* *Montreal Neurological Inst., McGill Univ., Canada*

The total ACh content of excised whole brain falls with time. Dropping the tissue into liquid air causes considerable decrease in the ACh content, apparently because sudden cold releases free ACh from the bound form and free ACh is destroyed by cholinesterase before freezing is complete. Free ACh is liberated in large amount when an eserine-containing brain suspension is poured into liquid air. The total ACh content of brain from eserinizated animals is not lowered by freezing in liquid air. Eserine administration causes a large increase, similar to that produced by anesthetics (reported in another communication), in the total ACh found in brain extracted by acid medium 3 minutes after decapitation. The bound ACh content of whole brain slices rises rapidly on incubation in Ringer-bicarbonate glucose medium to a much higher value than is found in brain extracted soon after excision. It seems that the value found for incubated slices may represent the maximal potential ACh content of the tissue. When total and free ACh are determined on halves of the same brain, by homogenizing initially in acid and neutral eserine-containing medium respectively, the free ACh found is a somewhat variable fraction, averaging 33% of the total but is not significantly dependent upon whether the total is 'normal' or elevated by Nembutal or eserine administration. Since, in the absence of eserine, brain very rapidly destroys added free ACh it is probable that the free ACh found is liberated in the process of homogenization.

Mechanism of fluoroacetate inhibition WILLARD B. ELLIOTT* AND GEORGE KALNITSKY *Dept. of Biochemistry, State Univ. of Iowa College of Medicine, Iowa City*

Citrate oxidation by a washed kidney cortex preparation was inhibited by fluoroacetate under conditions similar to those necessary for the formation of citrate from acetate. Previous workers (KALNITSKY AND BARRON *Arch. Biochem.* 19:75, 1948; KALNITSKY *Arch. Biochem.* 17:403, 1948) have shown slight inhibition of citrate in the presence of fluoroacetate. However, when the tissue preparation was incubated with 0.003 M fluoroacetate (9 μM) plus 5 μM oxalacetate for 15 minutes prior to the addition of citrate, 93% inhibition of citrate oxidation was observed. Under

the same conditions, the oxidation of *cis*-aconitate and isocitrate were not inhibited. The inhibition of citrate oxidation by fluoroacetate was shown to be competitive. The citrate formed in the presence of fluoroacetate and oxalacetate was isolated as the calcium salt after adding an excess of normal citrate as carrier. Fluoride was identified in the citrate formed, and in the pentabromacetone derived from the citrate. The inhibition of citrate oxidation and acetate oxidation is of the same magnitude. It is believed that the small amounts of fluorocitrate formed interfere with the conversion of citrate to *cis*-aconitate. The observed inhibition of citrate oxidation could account for the inhibition of acetate oxidation via the tricarboxylic acid cycle and the accumulation of citrate in systems poisoned with fluoroacetate, as observed by other workers.

Role of serine and acetate in uric acid formation

DAVID ELWYN* AND DAVID B. SPRINSON, *Dept. of Biochemistry, Columbia Univ., New York City*

L- and D-serine labeled with C^{14} in the β carbon atom and N^{15} in the amino group, and carboxyl labeled acetate were administered to pigeons. Uric acid, isolated from the excreta, was degraded and the isotope content in each position determined. It was found that the β carbon atom of L-serine is utilized for the ureide carbon atoms of uric acid to about the same extent as is the nitrogen for position 7. The incorporation of the β carbon into the ureide positions is about the same as that of formate (SONNE, BUCHANAN AND DELUVA *J. Biol. Chem.* 173: 69, 1948; KARLSSON AND BARKER *J. Biol. Chem.* 177: 597, 1949). The utilization of serine nitrogen for position 7 is close to that of the α carbon atom of glycine for position 5 (KARLSSON AND BARKER, *ibid.*). A limited incorporation of C^{14} into position 5 took place with either L- or D-serine. This may be explained by conversion of serine to pyruvate (CHARGAFF AND SPRINSON *J. Biol. Chem.* 148: 249, 1943), randomization of the isotope via the Krebs cycle and subsequent conversion through serine to glycine. This is in accord with the finding that β -labeled serine is converted rapidly to acetate in the rat. The reported utilization of the carboxyl carbon of acetate for the formation of the ureide carbon atoms of uric acid could not be confirmed. The significance of these findings to the metabolism of serine, glycine and formate, and the biosynthesis of uric acid will be discussed.

In vivo and in vitro studies with oxythiamine and neopyrithiamine. ALBERT J. EUSEBI* AND LEOPOLD R. CERECEDO, *Dept. of Biochemistry, Fordham Univ., New York City*

In mice maintained on one γ of thiamine/day, oxythiamine and neopyrithiamine have been

found to be potent antagonists of this vitamin. At molar concentrations of thiamine/oxythiamine of 1/25 mice succumb after 3-4 weeks, without manifesting the typical symptoms of polyneuritis. Neopyrithiamine was found to be more toxic, and produced typical thiamine deficiency signs at molar concentrations of thiamine/neopyrithiamine of 1/5. At this level, mice succumb after approximately 9 days. In studies on the mechanism of oxythiamine inhibition, the necessity of the alcoholic hydroxyl group on the thiazole moiety for inhibition was demonstrated in mice in which bromoxythiamine was injected at high levels. At a concentration 20 times greater than that at which oxythiamine was found to be toxic, no harmful effect of the bromoxythiamine was observed. The synthesis of oxythiamine-diphosphate afforded an excellent means of studying the mechanism of carboxylase action. With the aid of a purified enzyme system from brewer's yeast, it was found that 262 γ of oxythiamine-diphosphate produced a 77% inhibition of pyruvate decarboxylation in the presence of 4 γ of cocarboxylase. Oxythiamine-monophosphate and neopyrithiamine were inactive in this system. Further experiments showed that oxythiamine also inhibited the phosphorylation of thiamine, thereby preventing the synthesis of cocarboxylase. A similar inhibition of cocarboxylase formation by *P. pentosaceum* was observed in the presence of oxythiamine.

Analysis of the ribonucleic acid of the large cytoplasmic granules (mitochondrial fraction) of beef pancreas. JAMES L. FAIRLEY, JR.,* HARRY L. SEAGRAN* AND HUBERT S. LORING, *Dept. of Chemistry and Stanford Univ. School of Medicine, Stanford University, Calif.*

Beef pancreas was homogenized with 0.88 M sucrose in a Waring Blendor, and the large granule fraction isolated by differential centrifugation. Acid-soluble substances and lipids were removed by extraction with ice-cold, trichloroacetic acid, alcohol and hot 3:1 alcohol-ether. The ribonucleic acid was converted to monoribonucleotides with alkali, and the acid-insoluble constituents removed by precipitation with trichloroacetic acid. Acid hydrolysis of the ribonucleotide fraction and subsequent treatment with silver sulfate were employed to separate the purine bases from the pyrimidine nucleotides. After removal of silver ion from the pyrimidine fraction, cytidylic and uridylic acids were determined from UV absorption data. The purine bases were extracted from the silver-purine precipitate with 0.1 N HCl, and the concentration of guanine and adenine determined from the UV absorption of the resulting extracts. Total purine was also determined by Kjeldahl nitrogen and guanine by the colorimetric

method of Hitchings. Analyses performed in this way on several different preparations of mitochondria from beef pancreas yielded consistent values. The molar ratio of guanine to adenine averaged 1.6 as compared to values of 3 or 4 to 1 as reported previously for nucleic acid preparations from whole pancreas. The molar ratio of cytidylic acid to uridylic acid averaged about 1.3 as compared to values of 1.4 to 3.3 as reported by Kerr *et al* [*J Biol Chem* 181: 773, 1949] for different ribonucleic acid fractions obtained from beef pancreas. The present results suggest relatively large differences in the chemical composition of the various ribonucleic acid components of pancreas.

A phosphorylase in skeletal muscle which synthesizes glycogen directly IRWIN FEIGIN, JEROME FREDRICK AND ABNER WOLF (introduced by HANS T. CLARKE) *Veterans Administration Hospital, Bronx, Depts of Pathology and Neurology, Columbia Univ, and Neurological Inst, New York City*

Holophosphorylase, a phosphorylating enzyme which differs from the muscle phosphorylase previously described, has been crystallized from rabbit skeletal muscle. This enzyme synthesizes a polysaccharide which is soluble in water, is precipitated from solution by alcohol, does not reduce copper reagents until after acid hydrolysis, gives a red-brown color with iodine, and serves to prime and activate the phosphorylase reaction. In these properties, the polysaccharide resembles glycogen, rather than the amylose synthesized by muscle phosphorylase. Holophosphorylase differs also in that it is slightly activated by 0.0024 M phlorizin, while muscle phosphorylase is inhibited. These properties also characterize the enzyme in muscle homogenates. The crystals in which holophosphorylase activity is present, are hexagonal in shape, in contrast to the acicular crystals of muscle phosphorylase. It is suggested that holophosphorylase is the form of enzyme normally present in muscle, and that its molecular structure is altered in the extracting and concentrating procedures used to crystallize muscle phosphorylase. The possibility exists that similar alterations of molecular structure may occur in the concentration and crystallization of other enzymes.

Site of the influence of biotin on citrulline synthesis GLADYS FELDOTT,* PATRICIA MACLEOD* AND HENRY A. LARDY *Dept of Biochemistry, College of Agriculture, Univ of Wisconsin, Madison*

Previous studies have shown that biotin deficient animals fix less $C^{14}O_2$ into their tissue arginine, aspartic acid, guanine and citric acid than do normal rats. The washed residues of liver homogenate from biotin deficient rats synthesize citrulline from ornithine only one third to one half as fast as the same type of preparation from normal rats (*J Biol Chem* 180: 1003, 1949). Cohen and Grisolia have shown that the glutamic acid which is required for citrulline synthesis apparently functions by being converted to carbamyl glutamic acid. To trace further the specific site at which biotin influences the overall fixation of CO_2 into arginine, a study has been made of the reactions involving carbamyl glutamic acid. In the presence of glutamate, the average rate of citrulline synthesis from ornithine by washed liver residues from 14 biotin deficient rats was $0.24 \mu M/mg$ N. The corresponding rate for the pair-fed control animals was $1.38 \mu M/mg$ N which was not significantly different from that of stock rats ($1.28 \mu M/mg$ N). In the presence of carbamyl glutamate, the same liver preparations synthesized 1.34, 1.35 and 1.61 μM of citrulline/mg N respectively. It would appear that the limiting reaction in biotin deficient tissue is one involving the formation of carbamyl glutamic acid since subsequent reactions in the synthesis of citrulline proceed at the normal rate. *In vitro* additions of 'biocytin' and of another partially purified 'bound-biotin' preparation were ineffective in stimulating citrulline synthesis by liver tissue from biotin deficient rats.

Electrophoretic studies of an in vitro reaction between adenosine and rat serum MARIE A. FISCHER (introduced by W. S. McELROY) *Dept of Physiological Chemistry, Univ of Pittsburgh School of Medicine, Pittsburgh, Pa*

Incubation of adenosine in rat serum in a nitrogen atmosphere resulted in a decrease in the electrophoretic albumin area and an increase in the α_1 -globulin area of the serum. There was essentially no change in the total electrophoretic area or in the combined area of the albumin and α_1 fractions, however, the α_1 component had a slower mobility than the α_1 -globulin peak of control serum. Maximum reaction was obtained in 5 hours of incubation when 4 mg of adenosine was dissolved in 5 ml of serum. Larger amounts of adenosine did not increase the extent of the reaction. Practically no electrophoretic change occurred when the incubation was carried out under an atmosphere of 95% oxygen and 5% carbon dioxide. α -ketoglutarate reacted spontaneously with adenosine and thus prevented the reaction from taking place. Neither glutamate nor glutamine caused any inhibition but complete inhibition was obtained with glutathione. A similar change took place when ATP or adenylic acid were incubated with rat serum, however, adenine, hypoxanthine and xanthine were inactive.

Reaction of chymotrypsin with diisopropylfluorophosphate and with tetraethylpyrophosphate
J H FLEISHER,* B J JANDORF, W H SUMMERSON AND D P NORTON * *Biochemistry Section, Medical Division, Army Chemical Center, Md*

We have confirmed the findings of Jansen *et al* (*Federation Proc* 8 210, 1949) that the reaction between the enzyme chymotrypsin and diisopropylfluorophosphate (DFP) produces a crystallizable, enzymatically inert protein, containing phosphorus and isopropoxy groups, in the approximate proportion of two of the latter to one of the former, and their verbal report that treatment of this protein with periodate yields significantly less acetaldehyde than is obtained from native chymotrypsin by the same procedure. Similar results are obtained when chymotrypsin reacts with tetraethylpyrophosphate (TEPP), the enzymatically inactive protein yields less acetaldehyde after periodate treatment, and contains 2 ethoxy groups/m of bound phosphorus. Furthermore, the decrease in yield of acetaldehyde, and the amount of phosphorus and alkoxy groups bound/unit weight of enzyme, are the same when either DFP or TEPP reacts with chymotrypsin. This supports the view expressed previously (JANDORF *et al Abstracts*, Sept 1949 meeting of the American Chemical Society) based in part on manometric measurement of the rate and extent of reaction between chymotrypsin and both DFP and TEPP, that these 2 substances react with the enzyme in fundamentally the same manner, differing chiefly in rate, the combination with the enzyme in the case of DFP involving the splitting of the P-F bond whereas for TEPP the P-O-P bond is split, liberating one equivalent of acid in each instance.

Differential heat, alkali and trypsin inactivation of pancreatic lipase PAUL J FODOR (introduced by HAROLD P MORRIS) *Natl Cancer Inst, Natl Insts of Health, Bethesda, Md*

A fractionation of the pancreatic extract could be made whereby one fraction which was relatively thermostable and which acted upon the glycerides and another which acted upon the monovalent alcohol and glycol esters could be distinguished. Treatment of fractions of pancreas homogenates at various degrees of alkalinity resulted in a separation of the activities toward the glycerides on the one hand, and toward the monovalent alcohol and glycol esters on the other. Incubation of pancreas fractions with crystalline trypsin reduced the rate of enzymatic hydrolysis of the monovalent alcohol esters, the glycol ester and triacetin nearly to zero, whereas the extent of the hydrolysis of all the other glycerides was reduced to no more than 50%. This procedure was employed to isolate from pancreas homogenates a

protein exhibiting activity almost exclusively toward these glycerides. The coexistence in pancreatic extracts of at least 2 ester hydrolyzing enzymes is therefore suggested.

Brain proteolipides, a new group of protein-lipide substances soluble in organic solvents and insoluble in water J FOLCH AND MARJORIE LEES * *McLean Hospital, Waverley, Mass and Harvard Med School, Boston, Mass*

Brain and brain tumors contain compounds of a new type to which the name of proteolipides has been given. They are substances having as constituents a protein moiety and a lipide moiety combined in such a form that the resulting compounds are soluble in chloroform and/or chloroform-methyl alcohol mixtures and insoluble in water. Proteolipides are extracted quantitatively from the tissue by chloroform-methyl alcohol mixtures. From white matter, 3 different ones have been obtained (A, B, and C). A and B are soluble in chloroform-methyl alcohol mixtures and have the property of concentrating at chloroform-water interphases. C is soluble in chloroform. B is a crystalline compound which consists of 55% protein and 45% lipide. A and C are powders and do not appear yet to be pure compounds. The protein moiety from each one of them can be separated as follows. The proteolipide is dissolved in a chloroform-methyl alcohol mixture and 5% water added to the solution. The solution is taken to dryness. This destroys the bond between the constituent lipides and protein. The lipides are extracted from the residue with chloroform. The insoluble remnant is a denatured protein material which contains, in all cases, 14% N and 1.76% S. 91% of the N can be identified as amino acids after adequate hydrolysis. It is possible that the same protein moiety is present in each of the proteolipides studied.

Chemical and physical properties of tomatine and tomatidine THOMAS D FONTAINE, J S ARD,* ROBERT MA,* C L OGG* AND C O WILLITS * *Bureau of Agricultural and Industrial Chemistry Agricultural Research Center, Beltsville, Md and Eastern Regional Research Lab, Philadelphia, Pa*

Tomatine, a glycosidal alkaloid, and its aglycone, tomatidine, have previously been reported to possess *in vitro* antifungal activity (*Arch Biochem* 18 467, 1948). More recently, Wilson *et al* (*Federation Proc* 9 1950) have determined the oral toxicity of these compounds. Their report shows essentially no toxic effects when albino rats were fed diets containing up to 0.04% of these 2 compounds for 200 days, likewise, subacute and acute oral toxicity results were favorable. Crude tomatine has been prepared from dried tomato leaves on a semi pilot plant scale. A rather unique

procedure has been developed for the crystallization of tomatine—namely, the crude tomatine has been dissolved in either hot ammoniacal 70–80% dioxane or alcohol, followed by the rapid addition of 1.5–2 volumes of boiling water, with vigorous stirring. Upon addition of the hot water, a precipitate first forms but then dissolves almost immediately, and at this point crystallization of tomatine occurs in the hot solution. Tomatine, on acid hydrolysis, yields tomatidine and reducing sugars. The sugars have been identified as glucose, galactose, and xylose. Tomatidine contains a single double bond and 2 active hydrogens. Other chemical and physical data, including infrared and ultraviolet spectra, are presented for tomatidine and its acetyl derivative, and structural comparisons are made with related compounds.

Inhibition by glucose of the synthesis of proline from glutamic acid M. FORBES* AND M. G. SEVAG, *Dept. of Bacteriology, Univ. of Pennsylvania School of Medicine, Philadelphia*

In a synthetic amino acid medium free from glucose, glutamic acid (675 γ /ml) serves as precursor for the synthesis of proline associated with the growth of *Staphylococcus aureus* (strains 1A, 1E, 3A). *Staphylococci* fail to grow in the combined absence from the medium of glutamic acid and proline. Growth occurs in the presence of glucose when glutamic acid is omitted alone or together with one of the following amino acids—alanine, aspartic acid, lysine, and histidine, growth fails to occur when proline also is simultaneously omitted. Growth dependent on the synthesis of proline from glutamic acid likewise fails to occur when 5 mg of glucose or pyruvate/ml is added to the medium, showing that glucose or pyruvate blocks the reaction: glutamic acid \rightarrow proline. As little as 100 γ of glucose/ml causes 50% inhibition of this reaction. The inhibitory action of 5000 γ of glucose, or pyruvate/ml is counteracted by 1 γ of proline/ml. Ornithine or α -ketoglutaric acid were incapable of counteracting the effect of glucose. It is as yet not known whether proline bypasses the blockage, or functions as antagonist to glucose or pyruvate, or exercises a coenzyme-like effect.

The $2C_2$ condensation reaction in citric acid formation by a strain of *Aspergillus niger* J. W. FOSTER, S. F. CARSON* AND W. E. JEFFERSON*, *Biology Division, Oak Ridge Natl. Lab., Oak Ridge, Tenn.*

Previous demonstration of the $2C_2$ condensation reaction as a method of biosynthesis of C_4 dicarboxylic acids in fungi led to examination of its possible role in mold citrate formation. Radioactive citrate was produced from sucrose by *A. niger* in the presence of high specific activity methyl C^{14} -labeled acetate and $C^{13}O_2$. After purification

and isolation of the citrate as the calcium salt the citric acid was degraded. C^{14} and C^{13} specific activity were measured on each carbon atom of the citrate molecule. The data indicate that the C_4 dicarboxylic acid precursor of citrate arising from sugar can originate via the $2C_2$ condensation reaction.

Characteristics of water extractable apyrases obtained from various tissues SYLVIA FRANK AND RAKOMA LIPSHITZ (introduced by H. G. ALBAUM), *Dept. of Zoology, Columbia Univ., New York City*

Water extractable apyrases from muscle, liver, erythrocytes, plasma, and frog's eggs show characteristic and distinct pH activity curves. Optimum activity for muscle is found at pH 7.4, for liver at pH 4.5 and 9.2, for erythrocytes at 5.5 and 7.4, for plasma at pH 4.5 and 9.2, and for frog's eggs at pH 4.0 or lower and 9.2. Although some of these peaks are reminiscent of phosphatase pH optima reported in the literature, and NaF poisons the acid apyrase peak of liver as it does for acid phosphatase activity, little or no activity could be demonstrated under these experimental conditions when other substrates were substituted for ATP. The apyrase activity of erythrocytes from various sources (frog, chicken, rabbit, mouse, and human) shows a correlation between the amount of enzyme activity and the presence or absence of a cell nucleus. Attempts to separate nuclei from cytoplasm in chicken erythrocytes however show that apyrase activity is apparently associated with both cellular components. Dialysis of the water extractable apyrase from muscle results in a loss of activity which can be restored by re-introduction of the dialysate, concentrated by evaporation. The ashed dialysate fails to reactivate the enzyme. Boiled muscle extracts also activate the enzyme, and ashing destroys this ability. Crude preparations of Coenzyme A, magnesium, and glutathione and cysteine also stimulate enzyme activity. When the enzyme is saturated with magnesium or glutathione, the boiled extract continues to activate at a high rate suggesting the presence of an unknown co-factor.

Equilibrium and exchange reactions involving peptides, amino acids, and proteolytic enzymes IVAN D. FRANTZ, JR. AND ROBERT B. LOFTFIELD (introduced by LEWIS L. ENGEL), *Med. Labs. of the Collis P. Huntington Memorial Hospital of Harvard Univ., at the Massachusetts General Hospital, Boston, Mass.*

A method was recently reported (*Federation Proc.* 8:199, 1949) which makes possible the measurement of the small amount of peptide synthesized when an amino acid is incubated with a preparation of proteolytic enzymes. The first experiments with this system were carried out at

amino acid concentrations of 1 M, but more recent experiments at concentrations of 0.1 M have led to similar values for the free energy of the peptide bond. At these higher dilutions, the concentration of peptide formed amounts to only about 0.03% of the concentration of the amino acid added, and the detection of synthesis depends entirely on the use of labeled compounds. Data on the behavior of overloaded chromatographic starch columns will be presented, of interest in connection with the purification of materials present as traces mixed with large amounts of chemically similar compounds. Some evidence has been obtained, at present still somewhat equivocal, that when a peptide is allowed to split in the presence of labeled amino acids, the amino acid constituents of the peptide exchange with the free amino acids to produce, before equilibrium has been reached, a concentration of labeled peptide greater than that to be expected at equilibrium. With the enzymes which we have studied (a dipeptidase and a carboxypeptidase), this effect is slight.

Enzyme preparations from acetobacter suboxydans oxidizing inositol ROBERT E. FRANZL* AND ERWIN CHARGAFF, *Dept. of Biochemistry, Columbia Univ. College of Physicians and Surgeons, New York City*

In continuation of previous work on the oxidation of inositol stereoisomers by *Acetobacter suboxydans* (MAGASANIK AND CHARGAFF, *J. Biol. Chem.* 174: 173, 175, 929, 939, 1948) the enzyme system performing these oxidations has been studied in intact cells and in cell-free enzyme preparations. The latter were obtained by the differential centrifugation of phosphate buffer extracts of organisms crushed in a bacterial mill. Suspensions of the pellet sedimenting at 31,000 g in veronal or phosphate buffer oxidized meso-inositol with the utilization of $\frac{1}{2}$ M O_2 /M of substrate. The rate of oxidation was enhanced very strikingly by the addition of washed heat-inactivated bacteria to the enzyme solution. This effect could be partially duplicated by the addition of bacterial ash, or calcium and magnesium ions. This oxidation of meso-inositol, whose pH optimum is at pH 6.5, apparently requires an enzyme system related to the oxidases or, possibly, aerobic dehydrogenases. The oxidation of inositol stereoisomers and of other compounds by the cell-free enzyme preparations will also be discussed.

Comparison of vitamin B₁₂ and vitamin B_{12b} H. H. FRICKE,* BETTY LANIUS,* A. F. DEROSE,* M. LAPIDUS* AND D. V. FROST, *Abbott Labs., North Chicago, Ill.*

Crystalline vitamin B_{12b} was prepared from cultures of *Streptomyces griseus*. The compound showed absorption spectrum maxima at 274, 352, 411 and 526 mμ. Vitamin B_{12b} showed equivalent

activity in the assay with *L. leichmannii* and *E. coli* when compared with vitamin B₁₂. Rats maintained on a vitamin B₁₂ deficient diet gave similar growth responses upon the addition of either vitamin B₁₂ or vitamin B_{12b} to the diet. Dr. Tom Spies (personal communication) has demonstrated the clinical activity of vitamin B_{12b} for pernicious anemia, nutritional macrocytic anemia, and sprue. From clinical experience, vitamin B_{12b} appears to be equally as effective as vitamin B₁₂/γ in treating Addisonian pernicious anemia. On treating solutions of vitamin B₁₂ or vitamin B_{12b} with sodium bisulfite, both solutions exhibit identical absorption curves showing maxima at 275, 365, 418 and 515 mμ respectively. Removal of the sodium bisulfite indicates by absorption spectrum that vitamin B_{12b} is recovered from both solutions. Sodium hydrosulfite, depending on concentration, causes total or partial destruction of color and activity in solutions of vitamin B₁₂ and B_{12b}. The color is partially restored in presence of air if only small amounts of hydrosulfite are used. When crystalline vitamin B₁₂ or vitamin B_{12b} is injected intramuscularly into the rat, both can be recovered in their original form in the urine of the rat.

Distribution pattern of P³² in desoxyribonucleic acid-protein complex of intestinal tract mucosa FELIX FRIEDBERG (introduced by VERNON A. WILKERSON), *Dept. of Biochemistry, Howard Univ. College of Medicine, Washington, D. C.*

A variation in incorporation of S³⁵ of methionine into the protein of the intestinal mucosa along the length of the gastro-intestinal tract of dogs was reported recently (*J. Biol. Chem.* 173: 355, 1948). The incorporation in the stomach mucosa was low, and 3 peaks of activity were found in the intestinal mucosa. These peaks appeared in the region of the junction of the duodenum and jejunum, the junction of the jejunum and ileum, and in the large intestine. We obtained identical results when the desoxyribonucleic acid-protein complex was isolated after intravenous administration of inorganic P labeled with P³². Two female dogs (weighing 7.6 and 6.7 kg.) were injected i.v. with about 6 μc of P³² (as H₂PO₄). Food was removed 6 hours prior to the injection, and 4 hours after the injection the animals were killed. The entire gastrointestinal tract was removed and flushed with water, the mucosa (and submucosa) was obtained by pressure from the outside of the tract, and the P³² activity of the desoxyribonucleic acid-protein complex, isolated by the method of Schmidt and Thannhauser (*J. Biol. Chem.* 161: 83, 1945), suspended in acetone and dried, was determined.

Effect of amino acid antagonists on enzymes involved in nitrogen catabolism CARL FRIEDMAN

AND KARL DITTMER (introduced by R W JACKSON) *Dept of Chemistry, Florida State Univ, Tallahassee*

Since amino acid antagonists inhibit the growth of a variety of organisms, it seemed desirable to investigate their mode of action. The availability of several well defined enzyme systems involved in nitrogen catabolism permitted the study of the effect of some amino acid antagonists. The enzyme tyrosine decarboxylase (from *Strep faecalis*) acts on DL-phenylalanine at about 5% the rate observed with L-tyrosine in acetate buffer, pH 5.5, 28.5° C (conditions described by W W UMBREIT, W D BELLAMY AND I C GUNSALUS *Arch Biochem* 7 185, 1945). Phenylalanine antagonists such as β -2- and β -3-DL-thienylalanine are decarboxylated at rates somewhat less but of the same order of magnitude as phenylalanine. They do not reduce the rate at which tyrosine is decarboxylated. A preparation of 3,5-difluoro-tyrosine and 3-amino-L-tyrosine proved to be substrates with activities close to that of tyrosine. But 3,5-dibromo-L-tyrosine, 3,5-diiodo-L-tyrosine, and 3-nitro-L-tyrosine were inactive at corresponding enzyme concentrations as were other related amino acids such as p-tolyl-DL-alanine and p-hydroxyphenyl-DL-glycine. Results obtained with D-amino acid oxidase and other enzymes will also be presented.

Platinum catalyzed hydrogen-deuterium exchange with steroids DAVID K FUKUSHIMA* AND T F GALLAGHER *Sloan-Kettering Inst for Cancer Research, New York City*

We have investigated the platinum catalyzed exchange of deuterium for hydrogen with steroids in solution in acetic acid-d and D₂O at elevated temperatures. With saturated steroids containing ketone groups, an appreciable amount of stably bound deuterium was incorporated and the steroid was recovered in high yield. With increasing unsaturation or with multiple ketone groups, very much larger amounts of isotope were incorporated and in favorable instances high recovery of labeled steroid was possible. Hydroxylated steroids were less suitable for reaction since dehydrogenation and hydrogenolysis markedly diminished the yield. Acetylation led to lesser destruction without materially altering the exchange. Using Δ^4 -androsterone 3-17-dione, the effects of temperature, catalyst and substrate concentration have been investigated. Of these variables, temperature was most important since little exchange was effected below 100°. Greater incorporation of isotope was achieved when the steroid was present in relatively dilute solution. Variation in catalyst concentration gave slight differences in isotope concentration. These studies have led to the preparation of steroid hormones stably labeled with deuterium. The distribution of the isotope

has been investigated for cholesterol with 538 atoms % excess deuterium prepared by the exchange reaction according to Bloch and Rittenberg. All the isotope present in the steroid nucleus (46% of the total) was found in the vicinity of the Δ^5 -3-hydroxyl system while the isotope of the side chain (54%) was concentrated in the isopropyl group.

Comparative study on the phosphorylase content in homogenates of heart and striated muscle MARIA FULD* AND GERHARD SCHMIDT *Cardiac Lab, New England Center Hospital, Boston, Mass*

We have determined the respective amount of phosphorylase directly in homogenates of heart muscle and striated muscle of rats and rabbits. The tissues have been homogenized in the cold, dialyzed against running and distilled water until the disappearance of free phosphate and Mg⁺⁺. The dialysate has been diluted 25 times. Phosphorylase activity has been determined according to Cori, but the concentration of glucose-1-phosphate has been quadrupled. Under these conditions phosphoglucomutase and phosphatase do not interfere with the measurement. Striated muscle contains 12-20% more phosphorylase than heart muscle. These results confirm the findings of Shapiro and Wertheimer (*Biochem J* 37 397, 1943). These authors, however, worked with tissue extracts where the entire amount of enzyme present may not have been accounted for. For this reason the present study had been done on homogenates.

Conditions for determination of neutral 17-keto-steroids in urine O H GAEBLER AND WILLIAM T BEHER* *Edsel B Ford Inst for Med Research, Henry Ford Hospital, Detroit, Mich*

Continuing a study of factors affecting determinations of 17-ketosteroids (*Federation Proc* 8 182, 1949) we have sought to establish optimal conditions for the initial hydrolysis. The validity of using aqueous 5 N KOH in the Zimmermann reaction, when 2 color spectrophotometry is employed, depends upon these conditions, and was therefore investigated simultaneously, using the technique of Holtorf and Koch (*J Biol Chem* 135 377, 1940). Samples of pooled human urine were hydrolyzed for 6 different time intervals with each of 5 acids mentioned below. From ether extracts of the hydrolysates, neutral ketonic and non-ketonic fractions were prepared. After applying the Zimmermann reaction, extinction measurements were made at 515 m μ and 440 m μ . Optimal conditions of hydrolysis prevail when 1) the extinction at 515 m μ in the ketonic fraction is maximal, indicating good recovery, 2) the ratio E₄₄₀/E₅₁₅ in the non-ketonic fraction is constant over the required range of concentrations, 3)

changes produced by applying the procedure to pure solution of dehydroisoandrosterone are minimal. The best results were obtained when 150 ml aliquots of urine or solution, heated to boiling, were acidified with 22.5 ml of concentrated HCl, boiled for an additional 7 minutes, and cooled rapidly. Hydrolysis for 60 minutes with an equivalent concentration of H₂SO₄ satisfied the first 2 criteria listed above. Substituting equimolar amounts of HBr, HI, and H₃PO₄ for HCl yielded unsatisfactory results at all hydrolysis intervals. Results of analyzing 24-hour urines from 111 human subjects will also be discussed.

Carbon dioxide, inorganic phosphate and cation content of muscle in potassium deficiency

LITT I GARDNER, ELSIE A MACLACHLAN AND HELEN BERMAN (introduced by JAMES C ANDREWS) *Children's Med Service, Massachusetts General Hospital and Dept of Pediatrics, Harvard Med School, Boston, Mass*

Albino rats weighing 160-175 gm were fed a diet containing 0.003% K and 0.7% Na for 40 days. Controls were given the same diet plus added K. Measurements of skeletal muscle CO₂ and Cl concentrations showed no significant differences between the 2 groups. Muscle K was markedly reduced, whereas muscle Na, Mg, Ca and inorganic phosphate were significantly increased in the K deficient rats. Serum values for Cl were reduced and values for CO₂ were elevated in the K deficient group. When allowance was made for the Cl and CO₂ in extracellular fluid, the data indicated that in K deficiency there was a decreased concentration of CO₂ in intracellular fluid. If the latter represented a diminution in intracellular bicarbonate, partial compensation for this by increase in the inorganic phosphate as noted above seems a possibility. It is considered unlikely that Cl enters the cell, since it has previously been shown that K deficient animals are constantly in negative Cl balance. It is thought that the increased intracellular concentrations of the cations Na, Mg and Ca, which have transport rates relatively slower than K, necessitate reorganization of the ionic equilibria on both sides of the cell membrane. This may help explain the hypochloremic alkalosis of K deficiency.

Urinary excretion of thiosulfate by normal human adults JOSEPH H GAST, FRANK L ALDRICH AND KAZUO ARAI (introduced by HOWARD B LEWIS) *Dept of Biochemistry, Baylor Univ College of Medicine, Houston, Tex*

The urinary excretion of thiosulfate by adult humans has never been quantitatively established by reliable or specific methods. The reason for this is obvious even when one uses a specific precipitant for thiosulfate, such as the nickel ethylene diamine salt, because the amounts usually present

on a general mixed diet are below or at the limit of the end point error of the iodometric titration. This was established by a study of over 200 24-hour urine specimens. Application of a micro-quantitative procedure plus the use of radioactive thiosulfate enabled us to analyze both quantitative collections and random specimens for thiosulfate with the assurance of a definite recovery of the thiosulfate present. Replicate determinations indicate from 9-20 mg of thiosulfate sulfur to be present normally in 24-hour specimens, preserved with chloroform. Fresh random specimens, kept in the refrigerator indicate the presence of concentrations of the same order of magnitude ranging from 0.75-1.3 mg % thiosulfate sulfur. Values given are as determined, uncorrected for radioactive thiosulfate recovery. Isolation of nickel ethylene diamine thiosulfate from human urine with a small amount of added radioactive thiosulfate as tracer to follow losses in purification, delayed crystallization, etc will be reported together with detailed data from which the above figures were taken. Because of the ready oxidation of thiosulfate by certain tissues and organisms the data presented should suffice to require the explanation of its presence in any scheme for the oxidation of sulfur.

Influence of salt intake on chromatographic patterns of steroid excretion in essential hypertension JACQUES GENEST, GEORGE C COTZIAS, LEWIS K DAHL, WILLIAM EISENMENGER AND VINCENT P DOLE (introduced by R M ARCHIBALD) *Hospital of the Rockefeller Inst for Med Research, New York City*

Fresh urines were refluxed with 1/6 volume of concentrated HCl for 30 minutes. Their CCl₄ extracts were dried, dissolved in benzene, and aliquots chromatographed on alumina, and analyzed, according to the procedure already described for blood and urine steroids (*Federation Proc* 8:180, 1949). The analysis of such urine extracts from 3 subjects with essential hypertension maintained on high and low sodium chloride intake showed marked changes in the steroid patterns. These changes were observed in several of the fractions, but mainly in the ultraviolet absorptancy of the fraction eluted by water. An elevation noted at 268 mμ in the absorption curve of the first water fraction disappeared when the blood pressure was brought down to normal level. A subject with thalassemia minor and amoebiasis showed similar changes. Opposite, but less marked differences were observed in the cases of both a normal control and a subject with hepatic cirrhosis when placed on a high and low sodium chloride intake. The latter subject, on a 1 gm NaCl diet, showed no change in Na excretion after administration of DOCA and only slight modifications of the urinary steroid pattern.

Relation of ATP-ase and myosin JOHN GERGELY
(introduced by A SZENT-GYORGYI) *Natl Insts of Health, Bethesda, Md*

Myosin, prepared according to Szent-Gyorgyi was subjected to digestion by trypsin in order to investigate the relationship between ATP-ase activity and other characteristic properties of myosin. ATP-ase activity remained unchanged, while a decrease in the slope of the linear part of the specific viscosity-concentration curve indicated a decrease in the asymmetry of the myosin molecules. The ability of myosin to combine with actin also disappeared. By subjecting the trypsin digest to an isoelectric precipitation 2- to 3-fold increase in ATP-ase activity (Q_F) in the supernatant was achieved, with a 80-90% yield. Other procedures, including ultracentrifugation, did not bring about further purification. These experiments indicate that ATP-ase function is not essentially linked to the integrity of the myosin molecule.

Staphylocoagulase formation without plasma co-factor EARL B GERHEIM AND JULIA K GERHEIM
(introduced by ARNOLD G WARE) *Dept of Physiology and Pharmacology, Wayne Univ College of Medicine, Detroit, Mich*

Smith and Hale (*Brit J Exper Path* 25: 101, 1944) have explained coagulation by pathogenic *Staphylococcus aureus* as an activation of a bacterial component by a plasma component to form the active clotting agent. Although most investigators have accepted this thesis, actual proof of this mode of activation is lacking. Possibly, the bacteria might furnish the activator and the plasma the precursor. Miale (*Blood* 4: 1039, 1949) has stated that his preliminary observations would indicate that the precursor is found in plasma. In the experiments being reported we have been able to show repeatedly that staphylocoagulation is possible in the absence of the plasma factor. A 10% solution of the staphylococcal concentrate was placed at room temperature and over a 7 day period a portion was added to Armour's fibrinogen which has been shown to be free of what we wish to call co-factor (GERHEIM, FERGUSON AND TRAVIS, *Proc Soc Exper Biol & Med* 66: 525, 1947). Also the fibrinogen was adsorbed with barium sulfate to remove the prothrombin. While no staphylocoagulation took place initially, enough staphylocoagulase had formed at the end of 7 days to give a solid clot in less than 60 minutes. The precursor of the clotting agent (pro-staphylocoagulase), according to these results, appears to be of bacterial origin.

In vitro fatty acid metabolism and acetoacetate formation studied with C^{14} ROBERT P GEYER, MARY M CUNNINGHAM AND JOYCE PENDERGAST
(introduced by FREDRICK J STARE) *Dept of*

Nutrition, Harvard School of Public Health, and Dept of Biological Chemistry, Harvard Med School, Boston, Mass

Radioactive ($RC^{14}OOH$) pentanoic, hexanoic, heptanoic, octanoic, nonanoic and dodecanoic acids give rise to $C^{14}O_2$ and $CH_3C^{14}OCH_2C^{14}OOH$ when incubated with either liver or kidney slices.

The ratio $\frac{CH_3C^{14}OCH_2C^{14}OOH}{C^{14}O_2}$ is much higher

in the case of liver, but the total C^{14} in these products is similar for both tissues. This ratio is also much higher for the acids of an even number of carbons than for those of an odd number. This difference is mainly the result of more $CH_3C^{14}OCH_2C^{14}OOH$ being formed in the case of the even numbered acids. The ratio $\frac{CH_3C^{14}OCH_2COOH}{CH_3COCH_2C^{14}OOH}$ increases with increasing substrate chain length and is almost unity for dodecanoic acid. Studies with octanoic acids labeled in either the α - or β -position with C^{14} have also been done. Very little activity was found in the carboxyl of acetoacetic acid when the α -labeled acid was used. In the case of the β -labeled acid, both the amount and distribution of C^{14} in the respired carbon dioxide and the carbonyl and carboxyl of acetoacetic acid were the same as those observed with the carboxyl-labeled octanoic acid. The latter finding is strong evidence against the formation of acetoacetic acid by the alternate oxidation and cleavage of fatty acids. It supports the concept of C_2 -fragment formation and recondensation.

Effect of pH and ionic strength on biological activity of adrenocorticotrophic hormone (ACTH) B N GHOSH,* JOHN B RICHARDS,* MARSHAL MERKIN,* THOMAS W BURNS,* DOUGLAS M BROWN,* GEORGE SAYERS* AND EMIL L SMITH
Dept of Pharmacology and Lab for Study of Hereditary and Metabolic Disorders, Univ of Utah, Salt Lake City

Solutions of ACTH (10 $\mu g/cc$) were allowed to stand at room temperature for 19-24 hours, pH and ionic strength were varied (see table). Biological activity was determined by the adrenal ascorbic acid-depletion method in comparison with a standard at pH 1.0. JACTH and BNG35 were prepared according to the method of Sayers, White and Long. La-1-A was obtained from the Armour Laboratories. ACTH is remarkably stable at low pH. Hormonal activity is completely destroyed at pH 7 and at pH 13 in the absence of salt, sodium chloride and sodium phosphate appear to have some stabilizing influence. These stability studies have stimulated a complete re-evaluation of the physical properties of this hormone. Studies of the sedimentation and electrophoretic behavior will be presented.

PREP	pH	MEDIUM	ACTIVITY % STD (1 ERROR OF ESTIMATE)
La-1-A		5 M HCl	0
JACTH	0.1	1 M HCl	72(33-155)
BNG35	1.0	0.1 M HCl	85(62-117)
BNG35	4.1	0.1 M acetate	86(67-108)
BNG35	7.0	water	0
BNG35	7.0	0.15 M NaCl	43(27-69)
BNG35	7.3	0.038 M sodium phosphate	73(53-101)
BNG35	12.9	0.1 M NaOH	0
BNG35	12.6	0.1 M NaOH	18(12-29)
		0.15 M NaCl	
La-1-A		1 M NaOH	0

Studies on 'Dietary Factor' in experimental necrotizing arteritis BLAND GIDDINGS,* PHILIP L. HARRIS AND RUSSELL L. HOLMAN* *Dept of Pathology, Louisiana State Univ School of Medicine, New Orleans and Dept of Biochemistry Distillation Products, Rochester, N. Y.*

The sequence of feeding a 'standard high fat diet' for 8 weeks or longer then producing 'standard renal insufficiency' has been shown previously to regularly induce 'typical arterial lesions' in mongrel dogs regardless of age and sex. Either factor alone has proved to be ineffective. The pathogenesis of these arterial lesions, which closely resemble those of rheumatic arteritis and periarthritis nodosa, is obscure but is being studied from the standpoints of a 'dietary factor' and of a 'renal factor'. The dietary factor is defined as that substance (or substances) contained in the standard high fat diet which when followed by production of standard renal insufficiency, results in typical arterial lesions. From the studies thus far it would appear that the dietary factor is 1) found in certain animal fats (creamery butter and certain samples of cod liver oil), 2) not present in olive oil, corn oil, mutton tallow, lard, coconut oil and oleomargarine, 3) not vitamin A or vitamin D, 4) effective in quantities roughly proportional to the amount fed, 5) effective only if fed continuously since omission of it from the diet for 4 weeks or longer eliminates the response, 6) relatively heat stable, 7) destroyed or inactivated by saponification or by acetone separation, 8) inactivated or counteracted by vitamin E, or by cholesterol, or by substituting casein for liver in the standard diet, and 9) unaffected or not influenced by choline. Conjectures on its nature and mode of action will be presented.

Question of hyaluronidase in tumor tissue DAVID GLICK, LAWRENCE B. KIRILUK*, ERICK Y. HAKANSEN* AND ARNOLD J. KREMEN* *Depts of*

Physiological Chemistry and Surgery, Univ of Minnesota Medical School, Minneapolis

The possibility that hyaluronidase may be an agent that promotes the invasiveness of malignant cells and plays a role in the formation of metastases has led a number of investigators to examine cancer tissue for hyaluronidase activity. The reports were inconclusive and often inconsistent. A reinvestigation of this problem has been carried out on clean, non-necrotic samples of tumor tissue obtained directly from the operating room under sterile conditions. Precautions to maintain sterility were exercised throughout the preparation of extracts for the enzyme assay, and microbiological controls were run on all tissues and their extracts to detect possible contamination. In 4 different human benign tumor extracts, and 6 malignant, contamination was not found and no hyaluronidase could be detected. In most of the contaminated material from 25 other malignant tumors and as many samples of normal tissues the enzyme was present. Of 11 adenocarcinomas of the breast in mice, 5 yielded sterile extracts and no enzyme was found in them, while of the 6 contaminated extracts 4 contained hyaluronidase. The evidence indicates that the malignant cell contains no hyaluronidase unless it is contributed by microorganisms, and that previous claims for the presence of the enzyme were probably based on experiments in which contamination had occurred.

Vitamin E and hepatic necrosis MARIANNE GOETSCH, *Dept of Chemistry and Nutrition, School of Tropical Medicine, Univ of Puerto Rico, San Juan*

Preliminary tests confirm Schwarz (*Ann New York Acad Sci* 52:225, 1949) and Himsworth and Lindan (*Nature, London* 163:30, 1949) that vitamin E is a factor in hepatic necrosis of the rat on low protein diets. 21-day-old rats, with low stores of E, were given a diet containing 8.3% crude casein, 79.7% cornstarch, 6% lard, 2% cod liver oil, 4% minerals, and crystalline vitamins. 1) *Without a-tocopherol*. The rats died in 10-40 days, presenting massive hepatic necrosis. Alterations in lard content from 0-20%, without changing proportion of protein calories, were without effect. Choline and inositol apparently were not factors. The addition of 3% either methionine or cystine enabled rats to grow and survive until the present time (6 months of age) despite the onset of chronic muscular dystrophy and typical sterility. 2) *With 2 mg a-tocopherol per week*. All rats are surviving at 6 months of age. Those on the diet above grew poorly but were able to reproduce, although no young have survived the period of lactation. The young presumably died of starvation. The rats receiving in addition, .3% either methionine or cystine grew well and second generation young are

being reared. It is hoped to observe all rats until time of death.

Effect of anionic and cationic agents on urease

ROBERT L. GOLBY* AND GRANVIL C. KYKER
*Dept. of Biological Chemistry and Nutrition,
School of Medicine, Univ. of North Carolina,
Chapel Hill*

Experiments have been conducted to show the effect of certain anionic and cationic surface active agents on the rate of hydrolysis of urea by urease. Purified sodium dodecyl sulfonate and commercial trimethyl dodecyl ammonium chloride (Arquad 12, Armour and Company) have been studied at different levels in pH 7 phosphate buffer at 38°C. Both commercial preparations of urease and glycerol extracts of Jack Bean meal have been used. In each case the rate of hydrolysis in the presence of one of these agents was compared with a control which was run simultaneously. The liberated ammonia was determined as a measure of the extent of hydrolysis. Sodium dodecyl sulfonate depressed the activity of the enzyme in every case, 0.016 M sulfonate inhibited the hydrolysis approximately 20% when three-fourths of the urea in the control was hydrolyzed. When equimolar quantities of the sulfonate and Arquad 12 were added to the same reaction mixture, the depression of the reaction rate was not observed. When the Arquad 12 was used alone, a slight depression was usually observed but the data are less conclusive in this series of experiments.

Ultracentrifugal stratification of human serum lipoproteins

WILLIAM H. GOLDWATER, MALCOLM L. RANDOLPH, J. R. SNAVELY, ROY H. TURNER AND WALTER G. UNGLAUB (introduced by W. B. WENDEL) *Depts. of Medicine and Physics, Tulane Univ., New Orleans, La.*

The ultracentrifuge quantity rotor has been used to study the sedimentation characteristics of human serum lipid and protein components. Pooled normal sera are spun in plastic tubes, which are then frozen, sectioned at various levels, and homologous fractions from a number of tubes combined for analyses. Total protein concentration increases in a logarithmic type of curve towards the bottom of the tube. Albumin comprises the major portion of protein in the top half of the tube, increasing towards somewhat constant values at the bottom. Globulin concentrations are low in the top of the tube, but rise rapidly towards the bottom. Lipid components show peak concentrations at various levels in the tube, these maxima corresponding in most cases to specific gravity levels characteristic for each component. Free and ester cholesterol show predominant maxima at a specific gravity of about 1.017, with a smaller cholesterol ester peak at 1.060. Phospholipid maxima are observed at about

1.020, 1.045–1.050, and either 1.085 or the bottom-most portion of the tube. Neutral fat peaks occur in the top- and bottom-most portions of the tube, as well as at specific gravity levels of 1.010–1.020, 1.035, and 1.060. These findings are interpreted in the light of the existence of human serum lipids as lipoprotein aggregates, and the positive and negative sedimentation of these aggregates in various portions of the specific gravity (total protein) gradient produced by the ultracentrifugal process.

Response of the serum level of hyaluronidase inhibitor and mucoprotein to stress

ROBERT A. GOOD,* THOMAS A. GOOD*, VINCENT C. KELLEY* AND DAVID GLICK *Depts. of Physiological Chemistry and Pediatrics, Univ. of Minnesota Med. School, Minneapolis*

In previous studies in these laboratories we have demonstrated that the serum levels of both the non-specific hyaluronidase inhibitor and a mucoprotein fraction are elevated in a variety of the same clinical conditions. It appeared to us that all of the situations in which the serum levels of these two entities were elevated might be interpreted as stress situations and that an adrenal mechanism might be implicated. During these studies it has become apparent that elevations in the serum non-specific hyaluronidase inhibitor level can be evoked by subjecting an animal to stress by the Arthur phenomenon, the Shwartzman phenomenon, acute or chronic chilling, sterile ferrie chloride abscess, hyperimmunization or sterile tissue destruction by electrocautery. Serum mucoprotein was elevated by chronic chilling and by hyperimmunization but not by the other stimuli mentioned. Injection of lipoadrenal extract slightly raised the hyaluronidase inhibitor but decreased the serum mucoprotein. Injection of cortate in sesame oil and of sesame oil alone caused no effect on the hyaluronidase inhibitor but the cortate decreased the serum mucoprotein. Injection of adrenalin did not change the hyaluronidase inhibitor but did raise the serum mucoprotein. Adrenalectomy per se decreased the hyaluronidase inhibitor but did not affect the serum mucoprotein. Mock operation had no effect on either hyaluronidase inhibitor or mucoprotein, nor did anesthesia by intravenous sodium nembutal. Adrenalectomized animals, when exposed to chronic chilling, exhibited no elevations of the hyaluronidase inhibitor whereas mock operated animals did.

Accumulation of 5(4)-amino-4-(5)-imidazolecarboxamide in relation to sulfonamide bacteriostasis and purine metabolism in *Escherichia coli*

JOSEPH S. GOTS (introduced by CECILIA RIEGEL) *Dept. of Bacteriology, School of Medicine, Univ. of Pennsylvania, Philadelphia*

It is known that 5(1)-amino-4(5)-imidazole-carboxamide accumulates in *Escherichia coli* cultures under sulfonamide bacteriostasis. We have found that maximal accumulation occurs in systems showing 50-60% inhibition of growth. Accumulation of the carboxamide becomes evident 2 hours after inoculation and increases at a rapid rate until maximum is reached in 24-48 hours. No conditions have yet been found which will bring about any measurable utilization of the carboxamide after it is formed or when added from without, nor will the compound support the growth of seven *E. coli* mutants which require purines for growth. *p*-aminobenzoic acid when added at intervals after inoculation will immediately relieve growth inhibition and accumulation of the carboxamide but the quantity which has already accumulated remains constant. Pteroylglutamic acid has no effect on either the growth inhibition by sulfadiazine or accumulation of the carboxamide. Methionine or vitamin B₁₂ will relieve growth inhibition by low concentrations of sulfadiazine without relieving the accumulation. Of the numerous substances tested, the most marked effect on the accumulation of this compound was found in the presence of the purines, xanthine, adenine and guanine, which in concentrations as low as 2 to 4 µg/ml will prevent accumulation almost 100% without relieving growth inhibition. The hypothesis that 5(4)-amino-4(5)-imidazole-carboxamide is a normal intermediate in the biosynthesis of purines may be valid, but the data presented here cannot support it. A more likely explanation may be that this compound is an abnormal by-product brought about by an alternate pathway after normal metabolic pathways are blocked by sulfonamides.

Effect of dietary cholesterol on hepatic cholesterol synthesis R. GORDON GOULD AND C. BRUCE TAYLOR * *Rush Depts. of Biochemistry and Pathology, Presbyterian Hospital, Chicago, Ill*

Dogs and rabbits were maintained on high cholesterol diets for 6 weeks and the relative rates of cholesterol synthesis by liver slices determined by incubation with C¹⁴ labeled acetate followed by isolation and assay of cholesterol. Comparison with control animals showed that dietary cholesterol suppressed hepatic synthesis to a few per cent of the control rate in both rabbits and dogs. *In vivo* synthetic rates were also compared by administering labeled acetate by stomach tube and isolating cholesterol from the blood 1 and 16 hours later and the results were in agreement with those from the *in vitro* studies. Comparison of the rates of hepatic synthesis between animals of different species on cholesterol-free diets, together with data on cholesterol excretion, suggests that the over all aspects of cholesterol metabolism pro-

ceed more slowly in the rabbit than in the other species studied, and it is suggested that this may account for the extreme hypercholesteremia observed in cholesterol-fed rabbits. By separation of free and esterified cholesterol, it was shown that the newly synthesized cholesterol was largely in the free form. Of the other tissues tested, only skin was found to possess cholesterol synthetic activity of the same order of magnitude as liver. Adrenal cortical tissue was found to be capable of cholesterol synthesis as previously reported by Srere, Chaikoff and Dauben, (*J. Biol. Chem.* 176: 829, 1948), but in the present experiments the amount synthesized by the adrenals was of negligible quantitative importance compared with that formed in the liver or in the skin.

Transphosphorylation in the absence of nucleotides HARRY GREEN* AND O. MEYERHOF *Dept. of Physiological Chemistry, School of Medicine, Univ. of Pennsylvania, Philadelphia*

As was shown recently (*Science* 110: 503, 1949) transphosphorylation from phosphate compounds of higher energy to those of lower energy in the absence of nucleotides occurs readily with alkaline intestinal phosphatase. It can be observed with the help of P 32 if energy rich P donors with labeled P are incubated with glycerol or sugar and inorganic phosphate together with phosphatase. This finding was extended to several more P donors like phosphopyruvate, nitrophenyl phosphate and also to acid phosphatase. Moreover, the formation of a phosphate-enzyme compound was investigated with P 32. The bearing of these facts for the mechanism of transphosphorylation and the establishment of the specificity of phosphatases will be discussed.

Mechanism of biosynthesis of purine G. ROBERT GREENBERG (introduced by HARLAND G. WOOD) *Dept. of Biochemistry, School of Medicine, Western Reserve Univ., Cleveland, Ohio*

The investigation of the hypoxanthine-synthesizing system of pigeon liver preparations (*Federation Proc.* 8: 202, 1949) has been continued. Employing C¹⁴ compounds as tracers several possible intermediates in this synthesis have now been separated by paper chromatography. Evidence will be presented that the synthesis of hypoxanthine involves the following overall reaction: NH₃, CO₂, glycine, formic acid, ribose-phosphate → intermediates → inosinic acid → hypoxanthine + ribose-phosphate. This mechanism is based in part on the following data: By specific activity versus time measurements and by balance studies it has been demonstrated that C¹⁴ formic acid is incorporated into inosinic acid prior to the formation of hypoxanthine; dilution experiments with added non-radioactive inosinic acid provide additional evidence for this observation. Addition of

ribose-phosphate or compounds forming ribose-phosphate frequently effected a threefold increase in the rate of incorporation of radioactive formic acid into inosinic acid. When carboxyl-labeled glycine was employed as a tracer, a C^{14} -containing component was separated which did not occur in simultaneous experiments with radioactive formic acid. This component apparently is not a known metabolic product of glycine. The nature of this fraction and its possible role in the reaction is being investigated. It has been shown that 4-amino-5-imidazole carboxamide per se is not involved in the synthesis of purine in this system.

Simplified serum alkaline and acid phosphatase method using phenolphthalein monophosphate substrate. ALEXANDER B. GUTMAN, *Columbia Research Service, Goldwater Memorial Hospital and Dept. of Medicine, College of Physicians and Surgeons, Columbia Univ., New York City*

The estimation of serum alkaline and acid phosphatases can be greatly simplified by use of suitable phosphoric ester substrates which on hydrolysis yield a chromogen that can be measured directly. Phenolphthalein diphosphate has been proposed for this purpose but since the phosphomonoesterases in question dephosphorylate pure diphosphoric esters slowly if at all, phenolphthalein monophosphate would seem more appropriate. The monophosphoric ester was synthesized by phosphorylating phenolphthalein in dry pyridine with 1 equivalent of freshly redistilled phosphorus oxychloride under controlled conditions. Phenolphthalein monophosphoric acid precipitated out on acidification. After dissolving with sodium bicarbonate, free phenolphthalein was removed by shaking with ethyl acetate. Reprecipitation with acid gives the monophosphoric ester in good yield and sufficiently pure for general use. The preparations are standardized by their rate of dephosphorylation by sera of known phosphatase activity and also by their optical density at 450 m μ , pH 9.0. Phenolphthalein monophosphate is rapidly hydrolyzed by both alkaline and acid serum phosphatases. With our present preparations, incubation for 14 minutes at pH 8.7 or 35 minutest at pH 4.9 gives activities for serum alkaline or acid phosphatases equivalent to those obtained in 1 hour with β -glycerophosphate or phenylphosphate respectively. The pink free phenolphthalein color is developed immediately with sodium carbonate. Units of phosphatase activity are read directly from a standard phenolphthalein transmittance-concentration curve. The method, in regular use for several years, is simple, rapid and gives results in normal and a wide variety of abnormal sera that are in good agreement with the standard methods.

Mechanism of thiamine destruction by bracken

fern J. R. HAAG, BARBARA STEARMAN*, P. H. WESWIG*, R. T. PIERCE* AND J. R. SCHUBERT* *Agricultural Exper. Station, Oregon State College, Corvallis*

Antithiamine activity in rations containing air-dried fern and the harmless nature of steamed fern have previously been noted. Confusion concerning the significance of results obtained by the thiochrome procedure was clarified by our finding (A. C. S., Sept. 1948, Portland, Oregon), that both raw and steamed fern suspensions rapidly adsorb thiamine from pH 4.5 buffers. Subsequently raw fern more slowly destroys thiamine by enzymatic activity. Studies of temperature and pH effects and inhibitors therefore yield complicated results. Thiamine removal is more rapid at 0°C than at 25°, due to adsorption. Enzyme activity is slow at 25°, increases to 60°, then decreases at 70° due to heat inactivation. Moist heat inactivation can be detected at 65°, and is complete at 100° in less than 30 minutes. Dry heat at 100° for 24 hours results in some 50% inactivation for rats. Some activity remains after 24 hrs. at 110°. Enzymatic activity increases from pH 2.0 to 5.5 or 6.5. Concentration and nature of buffers in which fern suspensions are incubated variously affect adsorption and enzymatic processes. Supercentrifuged H₂O extracts possess pronounced enzymatic activity only. Neopyrithamine inhibits both processes. AgNO₃ inhibits enzymatic activity. NaCN and NaF do not inhibit. Cysteine markedly stimulates enzymatic activity, cystine is slightly stimulating, methionine is without effect. Thiamine removed by raw fern is not available to rats, that removed by steamed fern can be recovered and is available. Raw fern does not destroy the value of thiamine for yeast fermentation.

Fluorescence scanner for evaluation of papergrams of adrenal cortical hormones. WILLIAM J. HAINES AND NORMAN A. DRAKE (introduced by M. H. KUENZING), *Research Labs. Upjohn Company, Kalamazoo, Mich.*

A rapid and convenient technique has been devised for evaluating and recording the papergrams of those adrenal steroids and related substances having strong absorption at about 2400 Å. No chemical reactions are involved, and 5 gamma or less of these compounds can be detected. The procedure involves the use of a stainless steel box (6 x 12 x 13 inches) containing an 8-watt germicidal lamp in the bottom and covered on top with a 6 x 12 inch piece of Vycor glass or a Corning #9863 filter. On top the box there is placed a special glass screen having a thin layer, on its under side, of du Pont zinc silicate phosphor #609, which emits a bright green fluorescence when exposed to 2537 Å light. A dried papergram is

placed under the fluorescing screen, thus in the path of the ultraviolet light. The locations of the steroids are seen immediately as non fluorescing spots. A permanent record of the chromatogram is made in a dark room by inserting a focal plane shutter near the top of the box, and replacing the fluorescent screen with a piece of contact printing paper. Again the papergram is in the light path when the lamps are turned on and the slit is drawn across the field. The contact paper is developed by standard photographic procedures. Since the papergram is not sacrificed by this process, it may be evaluated subsequently by other techniques or used for the actual isolation of its components.

Utilization of cystine in man W. KNOWLTON HALL, V. P. SIDENSTRICKER* AND NATHAN RIEVIS*
Depts of Biochemistry and Medicine, Univ of Georgia School of Medicine and Med Service, Oliver General Hospital, Augusta

L-cystine was administered to each of thirty fasting adult patients in amounts of 8 grams or 20 grams. In the essentially normal subjects, there was no significant change in the blood amino acid nitrogen levels or in blood urea nitrogen over a period of 4 or 5 hours. In 5 out of 6 cases of cirrhosis of the liver there was a small but consistent drop in the blood amino acid nitrogen level after administration of 8 grams of L-cystine. In 6 of 12 cases of cirrhosis or of diseases seriously involving the liver, after the administration of cystine the excretion of amino acid nitrogen in the urine was significantly higher than in the controls.

Method for the determination of proline plus hydroxyproline carboxyl nitrogen PAUL B. HAMILTON AND PRISCILLA J. ORTIZ* *Dept of Biochemistry, Alfred I. du Pont Inst Nemours Foundation, Wilmington, Del*

Proline and hydroxyproline are unaltered by nitrous acid when reaction is carried out in hot 6N HCl, while alpha amino acids are rapidly converted to alpha hydroxy derivatives. When hydrochloric acid hydrolysates of proteins are treated with nitrous acid, proline and hydroxyproline remain and can be determined by the ninhydrin method of Van Slyke, Dillon, MacFadyen and Hamilton (*J Biol Chem* 141: 623, 1941). In the method to be described, excess nitrous acid is decomposed by ammonium sulfamate and fractional amounts of N-nitroso proline and hydroxyproline, formed during the initial treatment with nitrous acid, are hydrolysed. Reaction of nitrous acid with some alpha amino acids yields products that interfere in the ninhydrin method but these are extracted by ether. Pure proline suffers a 3% loss, pure hydroxyproline a 4% loss of carboxyl nitrogen, but the losses are constant and repro-

ducible. Cystine, tryptophane, tyrosine, arginine, ornithine and citrulline give small positive errors but in most proteins positive errors contributed by these amino acids present, compensate for the loss of imino carboxyl nitrogen so that correction factors are unnecessary. The 2 mg of imino acid necessary for determination under optimal conditions is contained in 10 mg of gelatin or 50 mg of most other proteins. Several proteins have been analysed by this technique.

Uptake and conversion of radioactive iodine by thyroid gland in tourniquet shock in rats MILTON W. HAMOLSKY*, ZYGMUNT S. GIERLACH* AND H. JENSEN *Med Dept Field Research Lab Fort Knox, Ky*

A standardized method of tourniquet 'shock' in rats produced a 24-hour mortality of 84.7% (145 animals), therapy with 0.9% NaCl lowered this to 7.88% (91 animals). Tracer doses of I^{131} (5-15 μ c without carrier) were injected intravenously, thyroids analyzed for total and organic I^{131} (percentage of injected dose). In total I^{131} there was no significant difference between controls without tourniquets versus those with occlusion maintained for 3-23 hours. However, 1 hour after tourniquet release, glands contained 50% control values, 2 hours after release, 30% of control values, 16 hours after release, only 5.2% of controls. There was no significant difference in percentage organic conversion at 1 and 2 hours, only slight decrease in 16 hours. Of 27 animals treated with saline, injected with I^{131} 16 hours later, 17 had values 1.5-4 times untreated controls. Uptake by liver, spleen, kidney, gastro-intestinal tract showed no significant difference in shock versus controls, traumatized limbs contained 3-7% more I^{131} than control limbs. *In vitro* incubation of glands *in toto* did not reveal as marked changes—uptake and conversion 2 hours after tourniquet removal were equal to control values, 16 hours after removal, both were slightly, but significantly decreased.

Fixation of radioactive carbon dioxide in lysine and tyrosine by decarboxylase-enzymes of these amino acids MARTIN E. HANKE AND M. S. H. SIDDIQI* *Dept of Biochemistry, Univ of Chicago, Chicago, Ill*

When L-lysine is treated with its decarboxylase (acetone washed cells of *Bacterium cadaveris*) in the presence of $C^{14}O_2$, and the reaction is stopped when the decarboxylation is about half complete, the remaining amino acid, and also the CO_2 formed by its subsequent decarboxylation, contain radioactivity. This CO_2 fixation does not occur if the enzyme is first heated to 100°. The fraction of the lysine synthesized (or extent of CO_2 fixation) was calculated as the ratio of the radioactive counts of the remaining lysine (or the $BaCO_3$ obtained

from the CO_2 from its decarboxylation) to the radioactive counts of the BaCO_3 obtained from the residual medium CO_2 at the end of the partial decarboxylation. The extent of CO_2 fixation at pH 7.1 and an initial lysine concentration of 0.036 M is increased from 26 to 359 parts per million as the extent of decarboxylation is increased from 17 to 48%, it is greater at pH 6.2 than at 7.1, and increases with increasing initial concentration of the amino acid. The greatest extent of CO_2 fixation observed, 1 part in 200, occurred at pH 6.2, an initial concentration of 0.13 M lysine, and a degree of decarboxylation of 62%. Similar observations were made with tyrosine and its decarboxylase, but here the residual amino acid was not isolated. Added ATP had no effect on the CO_2 fixation in either lysine or tyrosine.

Enzymatic incorporation of CO_2 in oxalacetate

ISAAC HARARY,* J. B. VEIGA SALLES* AND SEVERO OCHOA. *Dept. of Pharmacology, New York Univ. College of Medicine, New York City*

Highly purified pigeon liver 'malic' enzyme (*J. Biol. Chem.* 174: 979, 1948) catalyzes reactions (1) $l\text{-malate} + \text{TPN}_{\text{ox}} \rightleftharpoons \text{pyruvate} + \text{CO}_2 + \text{TPN}_{\text{red}}$ and (2) $\text{oxalacetate} \rightarrow \text{pyruvate} + \text{CO}_2$, in presence of Mn^{++} . (1) has a sharp optimum at pH 7.4, (2) at pH 4.5. $\text{COOH}-\text{CHOH}-\text{CH}_2-\text{C}^{14}\text{OOH}$ is obtained when (1) proceeds in presence of C^{14}O_2 although little or no label is incorporated into added oxalacetate (OAA). This shows that free OAA is not an intermediate in (1). No radioactive OAA is formed when the enzyme catalyzes reaction (2) in presence of C^{14}O_2 . The same is true of bacterial preparations which catalyze (2) but not (1). This indicates that (2) is practically irreversible. Ready incorporation of C^{14}O_2 in OAA occurs, however, when Straub's malic dehydrogenase is added to 'malic' enzyme, OAA, TPN, and Mn^{++} , if a catalytic amount of malate is present. Malic dehydrogenase catalyzes reaction (3) $\text{OAA} + \text{DPN}_{\text{red}} \text{ (or } \text{TPN}_{\text{red}}) \rightleftharpoons l\text{-malate} + \text{DPN}_{\text{ox}} \text{ (or } \text{TPN}_{\text{ox}})$ and will form $\text{COOH}-\text{CH}_2-\text{C}^{14}\text{OOH}$ from C^{14} -malate. The sum of (1) and (3) is (4) $l\text{-malate} + \text{OAA} \rightleftharpoons \text{pyruvate} + \text{CO}_2 + l\text{-malate}$, i.e., $\text{OAA} \rightleftharpoons \text{pyruvate} + \text{CO}$ (Wood and Werkman reaction). Evidence for (4) was also obtained manometrically. CO_2 fixation in OAA in pigeon liver extracts with added ATP (*J. Biol. Chem.* 164: 455, 1946) may occur via reaction (4).

D_2O dilution space to measure body water—relation of body water to body size JAMES D. HARDY* AND DAVID L. DRABKIN. *Harrison Dept. of Surgical Research and Dept. of Physiological Chemistry, Grad. School of Medicine, Univ. of Pennsylvania, Philadelphia*

The D_2O dilution space, as a measure of total body water, was determined in 10 adult human subjects, ranging in size from very lean (male

of 60.9 kg mass and 91 cm height and female of 53.7 kg and 90.2 cm) to very obese (male of 121 kg and 90.2 cm and female of 86.4 kg and 76.2 cm). After equilibration of intravenously injected heavy water with the body water, the concentration of D_2O in the water distilled from plasma samples was obtained by means of accurate specific gravity determinations. The extracellular fluid and plasma spaces were also determined by means of sodium thiocyanate and the dye T-1824. The total body water and body mass were found to have an inverse relationship to each other. In percentage of body weight, body water varied from 70 (the commonly accepted value) in the abnormally lean to as low as 40 in the most obese. The volumes of extracellular fluid and plasma were more closely correlatable with total body water than with body mass. Evidence for a reciprocal relationship between water and fat is provided by our findings, and a revision of views as to the quantities of body fluids becomes necessary. An objective evaluation of overnutrition (excess fat) was derived from the nutritive index (COWGILL, G. R. AND D. L. DRABKIN. *Am. J. Physiol.* 81: 36, 1927). A nomogram has been constructed for the prediction of excess fat and total water content of subjects of widely different size.

Lactic acid oxidizing system of *Escherichia coli*

NIELS HAUGAARD (introduced by W. C. STADIE)

John Herr Musser. *Dept. of Research Medicine, Univ. of Pennsylvania, Philadelphia*

The mechanism of lactic acid oxidation by *E. coli* (strain B) has been studied. The organisms were grown in media containing DL-lactate as the source of carbon. Cell free preparations were obtained by exposing suspensions to sonic vibration. Such preparations under aerobic conditions were found to convert DL-lactic acid quantitatively into pyruvic acid. In experiments in which the reaction was allowed to go to completion an exact balance was obtained between the lactic acid added, the oxygen taken up, and the pyruvate formed. The entire metabolic activity was associated with particulate matter, the supernatant after high speed centrifugation having no activity. A complete hydrogen transferring system was apparently situated on the suspended particles since the preparations oxidized lactate in the absence of added hydrogen carrier. Addition of methylene blue did not further increase the activity. An acetone powder was prepared from the suspensions obtained by sonic vibration. A suspension of such an acetone powder was inactive in the absence of added methylene blue. When methylene blue was added it converted half of added DL-lactate to pyruvate. It was inactive in the presence of L-lactate. It is concluded that two enzyme systems are present in *E. coli*, one oxidis

mg D-lactic acid, the other L-lactic acid. Precipitation with acetone destroys the system oxidizing L lactic acid as well as part of the hydrogen transferring enzymes.

Hemoglobin, oxyhemoglobin and anhydro-hemoglobin FELIX HAUROWITZ, SAIDE TUNC* AND RADITE CINDI* *Dept of Chemistry, Indiana Univ, Bloomington, Ind*

Moist layers of oxyhemoglobin (HbO_2) exposed to low pressures are converted into hemoglobin ($\text{Hb} \cdot \text{H}_2\text{O}$), and, on evaporation of the water at low temperatures, into anhydro-hemoglobin (Hb), a hemochromogen-like substance with absorption maxima at 559 and 528 μ (v Zeynek 1926, Haurowitz, in *Hemoglobin* New York Interscience, 1949). Anhydro-hemoglobin dissolved in water in the presence of air furnishes HbO_2 which on reduction gives hemoglobin, but no hemochromogen. It is concluded that in hemoglobin one of the water molecules is bound to Fe, replacing the O_2 molecule in HbO_2 . The equilibrium of reaction (I) $\text{Hb} + \text{H}_2\text{O} \rightleftharpoons \text{Hb} \cdot \text{H}_2\text{O}$, was examined spectrophotometrically at different temperatures. The ratio $\text{Hb} \cdot \text{H}_2\text{O}/\text{Hb}$ was approximately 1.0 at 34°C and 22 mm Hg. Reaction (I) is reversible between 0° and 40°C. On the other hand, dry HbO_2 does not dissociate into Hb and O_2 , even when exposed to low pressure ($p_{\text{O}_2} = 0.06$ mm). We were not able, therefore, to determine experimentally the equilibrium constant of reaction (II) $\text{Hb} + \text{O}_2 \rightleftharpoons \text{HbO}_2$. This equation, (II), is the arithmetical sum of the above mentioned equation (I), and of equation (III) $\text{Hb} \cdot \text{H}_2\text{O} + \text{O}_2 \rightleftharpoons \text{HbO}_2 + \text{H}_2\text{O}$. Hence the equilibrium constant K_{II} is equal to $K_{\text{I}} \times K_{\text{III}}$. Using data of Roughton and Hartridge (1925, 1936) for K_{III} we find that K_{II} is approximately 10^3 . This high value of K_{II} is in accordance with the weak dissociation tendency of dry HbO_2 found in our experiments. Evidently O_2 is bound more firmly by Hb than is water. The higher affinity of Hb for oxygen is attributed to the covalent linkage of O_2 in the diamagnetic complex HbO_2 (Pauling and Coryell). The combination of hemoglobin with O_2 in aqueous solution is represented by equation (III) and not by (II).

Effect of body exposure to x-rays on rate of incorporation of C^{14} carboxyl-labeled alanine into mouse protein L. H. HEMPELMANN, S. CARR, I. D. FRANTZ, JR., R. MASTERS AND E. LANDIN (introduced by LEWIS L. ENGEL) *Med Labs of the Collis P. Huntington Memorial Hospital of Harvard Univ, at the Massachusetts General Hospital, Boston, Mass*

The influence of lethal doses of x-rays on the *in vivo* incorporation of C^{14} carboxyl-labeled alanine into the protein fraction of spleen, liver, and muscle was studied in young mice. Decarboxylation by means of the ninhydrin reaction was used

to determine the quantity of total and radioactive carbon in the free carboxyl groups of the amino acids in protein hydrolysates. The specific activity of C^{14} was unchanged in liver, spleen, and muscle protein of litter mates divided into control and irradiated groups when the alanine was given immediately after exposure and the animals killed 2 hours later. When the alanine was given 2 hours after exposure, the amount of incorporated C^{14} in the spleen protein was reduced in the irradiated groups. The total carboxyl carbon in the liver and spleen protein of irradiated animals was considerably less than that of controls 4 days after exposure. The specific activity in muscle and spleen protein was less in the irradiated than in the controls while the activity in the liver was greatly increased in the exposed animals. The distribution of C^{14} in the amino acid fractions of the liver protein of irradiated and control animals was determined by means of starch column chromatography.

The *in vivo* observations were largely confirmed by studies with spleen and liver slices, but differences from normal were less striking. The amount of C^{14} in the urea fraction of the liver slice media was greater in irradiated than in control experiments.

Effect of riboflavin and vitamin B_6 deficiencies on conversion of tryptophan and 3-hydroxyanthranilic acid to quinolinic acid L. M. HENDERSON, I. M. WEINSTOCK* AND G. B. RAMASARMA* *Division of Biochemistry, Noyes Lab of Chemistry, Univ of Illinois, Urbana*

Vitamin B_6 , thiamine, riboflavin, and folic acid deficiencies have been reported to reduce the urinary excretion of N^1 -methylnicotinamide and nicotinic acid following the administration of tryptophan to the rat. Urinary quinolinic acid accounts for a larger percentage of administered tryptophan or 3-hydroxyanthranilic acid than either nicotinic acid or N^1 -methylnicotinamide. Attempts to localize the reactions in which the vitamins are concerned have been made by studying the excretion of quinolinic acid in response to tryptophan and 3-hydroxyanthranilic acid. Control rats receiving a 9% casein diet excreted $11.0 \pm 1.1\%$ of the administered tryptophan and $12.7 \pm 2.0\%$ of the 3-hydroxyanthranilic acid as quinolinic acid. Rats acutely deficient in riboflavin excreted $1.06 \pm 0.08\%$ of the tryptophan and $7.3 \pm 1.6\%$ of the 3-hydroxyanthranilic acid as quinolinic acid, vitamin B_6 -deficient animals excreted only $0.73 \pm 0.16\%$ of the administered tryptophan and $8.8 \pm 1.1\%$ of the 3-hydroxyanthranilic acid as quinolinic acid. Results with pair-fed control groups indicated that inanition was not the cause of these changes. Thiamine-deficient animals and their pair-fed controls exhibited reduced conversion of

both tryptophan and 3-hydroxyanthranilic acid. Increasing the casein level of the diet from 9%–18% reduced the amount of administered tryptophan excreted as quinolinic acid to 3.0% for control animals and to 0.4% for vitamin B₆-deficient animals. These results suggest that riboflavin and vitamin B₆ function in the conversion of tryptophan to 3-hydroxyanthranilic acid and not in the conversion of the latter to quinolinic acid.

Specific nucleotidases LEON A. HEPPEL AND R. J. HILMOE * *Natl. Insts. of Health, Bethesda, Md.*

Studies have been carried out with enzymes from several sources that hydrolyze nucleotides containing phosphate in different positions. Preliminary experiments with potato extracts indicate the presence of a nucleotidase specific for adenosine-5-phosphate and another for adenosine-3-phosphate. Bull. seminal plasma, which rapidly dephosphorylates adenosine-5-phosphate (MANN *Biochem J* 39:451, 1945) was also investigated. A 50-fold purification of this activity was achieved by fractionation with salmine, ammonium sulfate and ethanol, and by adsorption with alumina C γ . The rate of liberation of inorganic phosphate from different compounds by seminal plasma and by the purified enzyme is given below. (The activity of both preparations is expressed on the basis of 100 for adenosine 5-phosphate.)

SUBSTRATE	ACTIVITY OF	
	SEMINAL PLASMA	PURIFIED ENZYME
Inosine-5-phosphate	115	113
Nicotinamide-ribose-5-phosphate	70	67
Ribose-5-phosphate	1.3	0.8
Adenosine-3-phosphate	2.0	<0.005
Sodium- β -glycerophosphate	1.0	0.02
Glucose-6-phosphate	0.8	<0.01

Guanosine-3-phosphate, riboflavin phosphate, fructose-1, 6-diphosphate, fructose 6-phosphate and 3-phosphoglyceric acid were hydrolyzed more slowly than glucose-6-phosphate by seminal plasma and the activity was greatly reduced on purification. These data would support the view that a single enzyme dephosphorylates the several compounds containing phosphate on position 5 of the ribose moiety. Snake venom has a nucleotidase of apparently similar substrate specificity but purification has been hampered by its instability.

Effect of cysteine and hydrogen sulfide on pteroylglutamic acid conjugase of hog kidney C. H. HILL AND M. L. SCOTT (introduced by L. C. NORRIS) *Cornell Univ., Ithaca, N. Y.*

Mims, Swendsen, and Bird (*J. Biol. Chem.* 170:367, 1947) reported that the inhibitory effect of nucleic acid upon the pteroylglutamic acid (PGA)

conjugase of hog kidney is overcome *in vitro* by the addition of cysteine or hydrogen sulfide to the enzyme system. These research workers stated that their findings suggested the presence of sulfhydryl groups in the PGA conjugase of hog kidney. In extending the studies of Mims *et al.* in this laboratory it was found that exceedingly low levels of hog kidney conjugase, which were completely inactive alone, exhibited maximum activity when cysteine was added to the enzyme system. Hydrogen sulfide also served as an activator of this system, but the rate of release of PGA was not increased with this substance to the same extent that it was with cysteine. Relatively high levels of cysteine were required to produce maximum activation of the enzyme. On the other hand, much lower levels of cysteine, which produced little activation alone, were completely effective when a low level of hydrogen sulfide was also added. The addition of sodium thioglycolate, which is known to inhibit cysteine de-sulfhydrase activity, completely inhibited PGA conjugase activation by either cysteine or hydrogen sulfide. These studies present further evidence indicating that the conjugase of hog kidney requires sulfhydryl groups. While hydrogen sulfide was shown to activate the enzyme, the results point to cysteine as the primary sulfhydryl donor. A possible explanation of the action of hydrogen sulfide is that this substance may transfer sulfhydryl groups to cysteine which in turn transfers them to the enzyme.

Inhibition of the 'oxalacetic oxidase system' in tissues adjacent to methylcholanthrene tumors ROBERT M. HILL, DORSEY E. HOLTKAMP* AND ENID K. RUTLEDGE * *Depts. of Biochemistry and Pathology, Univ. of Colorado Med. Center, Denver*

Potter, LePage, and Klug (*J. Biol. Chem.* 175:619, 1948) reported that "homogenates of several rat tumors showed negligible amounts of oxygen uptake when oxalacetate" was used as a substrate. Using a similar reaction mixture, and a transplantable methylcholanthrene induced fibrosarcoma of the thigh muscle of the rat, we were able to verify their observations. We have compared homogenates of these tumors with 1) homogenates of muscle tissue adjacent to the tumor, but not having a neoplastic appearance by histological examination and with 2) homogenates of corresponding normal muscle tissue from the opposite leg. The muscle tissue adjacent to the tumor shows some O₂ uptake but considerably less than does the corresponding normal tissue of the opposite leg. Observations have been made on 17 animals with methylcholanthrene induced tumors and on 23 animals in the first, second, and third generations of transplantation of these tumors.

Inhibitory effect of beef extract and 2-methylthio-

adenine on growth of typhoid bacillus G H HITCHINGS, G B ELION* AND M B SHERWOOD* *Wellcome Research Labs, Tuckahoe, N Y*

During routine tests of the antibacterial effects of purine and pyrimidine analogs, by the filter paper disk-agar plate technique, 2-methylthio 6-aminopurine was found to inhibit the growth of typhoid bacillus powerfully. When these tests were repeated, with substitution of a synthetic medium in the agar for the usual proteose peptone-beef extract mixture, no inhibition by the antagonist was observed, although no difference in growth on the 2 media could be detected. The addition of various substances to the synthetic medium resulted in re-appearance of the antibacterial effect of the analog. Beef extract is the most effective substance found to date, but liver extract and yeast extract have appreciable activities. The concentration of the beef extract factor was followed by preparing agar containing the synthetic medium and 2-methylthioadenine and seeding this with the typhoid bacillus. Growth on this medium is excellent, but zones of inhibition can be produced by the application of filter paper disks which have been dipped in beef extract solution. Paper chromatography of beef extract revealed the presence of at least 2 substances with activity. Fractional precipitation by alcohol and adsorption and elution from superfiltrol have resulted in a considerable concentration of the factor.

Synthesis and microbiological activity of higher aliphatic β -keto acids KLAUS HOFMANN, A E AXELROD* AND M A MITZ* *Dept of Chemistry, Univ of Pittsburgh, Pittsburgh, Pa*

In connection with studies on the relation of biotin and fatty acids, a number of higher β -keto acids were prepared and their microbiological activities determined. Although higher β -keto acids have been postulated as intermediates in the metabolism of fatty acids, little is known about their preparation and properties. Unsaturated members of the series have not been previously prepared. Highly purified fatty acids were converted into the corresponding β -keto esters containing 2 additional carbon atoms by the procedure of Stållberg-Stenhagen (*Archiv Kemi Miner Geol* 20A No 19, 1945). In view of the fact that the known procedures for the saponification of β -keto esters are highly unsatisfactory, a new procedure was developed which allows the preparation of β -keto acids in high yields. β -ketomyristic, palmitic, stearic and arachidic acids were prepared and characterized. Application of the same procedures to oleic acid leads to the synthesis of 3-keto $\Delta^{11,12}$ eicosenoic acid (oleoyl acetic acid). The β -keto acids and esters were tested for their ability to replace biotin for *Lactobacillus arabinosus*. The

saturated β -keto acids were inactive. Methyloleoyl acetate was as active as methyloleate in contrast to free oleoyl acetic acid which was practically inactive.

Alterations in tissue proteins of dogs following prolonged fasting ELMORE HOLMES* AND DEMPSEY B MORRISON *Dept of Chemistry, Univ of Tennessee, Memphis*

Proteins of heart, skeletal muscle, liver, kidney, and blood plasma were analyzed in the Tiselius-Longsworth apparatus. Dissected tissue was homogenized in a Waring blender. The homogenate was then frozen and thawed after which aliquots were taken for centrifugation (12,000 r p m), for determination of water content, total solids, and proteins (Kjeldahl), and for fractionation of the proteins by extraction. Proteins soluble in 0.12 M NaCl were first removed by repeated extraction. The residue was then similarly extracted with 1.0 M NaCl, and finally with 0.06 M NaOH. Only a small insoluble fraction remained after these successive extractions. All extractions were carried out at 3-5°. Total proteins were determined on each extract, on the final insoluble residue, and on the supernatant obtained by centrifugation. The supernatant fluids and saline extracts were also equilibrated against veronal buffer (pH 8.6) preparatory to electrophoresis. Representative electrophoretic patterns of the plasma and tissue extracts of well fed and fasted dogs will be shown. Alterations in the proteins as shown by fractional extraction and by electrophoretic analysis will be presented graphically.

Phosphogluconic acid metabolism B L HORECKER *Natl Insts of Health, Bethesda, Md*

The oxidation of 6-phosphogluconic acid was studied by Warburg and Christian and by Dickens and shown to require triphosphopyridine nucleotide (TPN). Several degradation products were obtained, none of which was positively identified. An enzyme has now been purified from yeast which quantitatively converts 6-phosphogluconate to pentose phosphate and CO_2 . The enzyme occurs in extracts of liver, kidney, brain, heart muscle and red cells, as well as in yeast maceration juice. The yeast enzyme has been purified 40-fold by a number of steps including acetone precipitation and fractionation with ammonium sulfate. With the purified enzyme pentose-phosphate accumulation was accomplished by means of the following dismutation:

- 1) 6-phosphogluconate + TPN \rightarrow
pentose phosphate + CO_2 + TPNH_2
- 2) pyruvate + $\text{TPNH}_2 \rightarrow$ lactate + TPN

In agreement with equation 1, one μ of pentose phosphate and one μ of CO_2 are produced/ μ of 6-phosphogluconate (or pyruvate) disappearing.

CO₂ production at intermediate stages in the reaction is equal to 6-phosphogluconic acid removal or pentose phosphate production, no accumulation of a 6-carbon oxidized intermediate is observed. The pentose phosphoric acid ester formed is hydrolyzed by a phosphatase purified by Dr L. A. Heppel from semen at a much slower rate than is ribose-5-phosphate. In glycylglycine buffer at pH 7.5 the rate of TPN reduction by 6-phosphogluconate is increased 5-fold by Mg⁺⁺ or Mn⁺⁺, or 2-fold by CN⁻. *Reaction 1* is used for the determination of 6-phosphogluconate.

Synthesis of rhodopsin from vitamin A₁ RUTH HUBBARD AND GEORGE WALD (introduced by J. T. EDSALL) *Biological Labs, Harvard Univ, Cambridge, Mass*

It has been believed since Kühne that the synthesis of rhodopsin from colorless precursors, now known to be vitamin A₁ and rhodopsin-protein, occurs only in the intact eye. This process has now been carried out *in vitro*. Intact retinas and retinal homogenates, incubated in the dark, regenerate about 10% as much rhodopsin from vitamin A₁ as is formed during dark adaptation *in vivo*. The addition of cozymase, or of a homogenate of the pigment layers of the eye, pigment epithelium and choroid, to a retinal homogenate approximately doubles the yield of rhodopsin. When both cozymase and pigment layer homogenate are added to a retinal homogenate, the yield is doubled again, approximating 40%. Aqueous retinal extracts to which cozymase and vitamin A₁ are added also synthesize rhodopsin in a yield of about 10%. The mechanism of these syntheses is not yet wholly understood. Retinal homogenates can oxidize vitamin A₁ slowly to retinene₁ (vitamin A₁ aldehyde) in the presence of an aldehyde-binding reagent such as hydroxylamine. In the retina, rhodopsin-protein is a specific retinene-binding reagent, condensing with retinene₁ spontaneously to form rhodopsin. One pathway for rhodopsin synthesis is therefore the oxidation of vitamin A₁ to retinene₁ by retinene reductase, coupled with the binding of retinene₁ by rhodopsin-protein to form rhodopsin. Cozymase promotes this process as the coenzyme of the retinene reductase system. Pigment layer homogenate may act upon the same system by supplying respiratory factors which drive it in the oxidative direction. Rhodopsin may also be synthesized by other mechanisms still to be explored.

Potentialiation of esterase activity of chymotrypsin by electrolytes BERNARD J. JANDORF *Biochemistry Section, Med. Division, Army Chemical Center, Md*

With commercial preparations of chymotrypsin no direct relationship was found between enzyme concentration and the rate of action on N-acetyl-

tyrosine ethyl ester as determined manometrically. The divergence from proportionality is due in part at least to a variable content of MgSO₄ in the enzyme preparations employed. When sufficient MgSO₄ is added to the reaction mixture, the esterase activity becomes proportional to the concentration of chymotrypsin. In addition to this effect, MgSO₄ increases esterase activity markedly, values exceeding the control activity by fivefold or more being obtained if sufficient salt is added. This effect of MgSO₄ can be duplicated by other salts, while no potentiation of esterase activity is found in the presence of non-electrolytes. On partial inactivation of chymotrypsin with diisopropylfluorophosphate, the enzymatic activity remaining is potentiated by salts to the same degree as that found for the completely active enzyme, this indicates that the activating effect of salts is not due to their rendering enzymatically active groups on the protein molecule more accessible to the substrate. When limiting amounts of substrate are employed, the presence of salt affects only the rate and not the extent of ester hydrolysis. No salt which was found to potentiate the esterase activity of chymotrypsin had any effect on the proteinase (casein hydrolysis) activity of this enzyme.

A crystalline, active oxidation product of α -chymotrypsin EUGENE F. JANSEN, M. D. FELLOWS NUTTING,* A. LAURENCE CURL* AND A. K. BALLS *Enzyme Research Division, Bureau of Agricultural and Industrial Chemistry, United States Department of Agriculture, Albany, Calif*

Crystalline α -chymotrypsin was found to contain an impurity which gave rise to acetaldehyde on oxidation with sodium periodate. The amount of this 'terminal threonine' varied from 0.5-1.0 M/M of enzyme, using 27,000 for the molecular weight of the enzyme. With just sufficient periodate (2.5 M/M of enzyme) to cause the maximum formation of acetaldehyde within one hour, no decrease in the activities (esterase and proteinase) occurred. Doubling this amount of periodate resulted in no more acetaldehyde, but in 60% destruction of the activities when assayed under conditions for α -chymotrypsin. Larger amounts of periodate (as much as 50 M/M of enzyme) caused no greater decrease. The oxidation product resulting from 5-10 M of periodate/M of enzyme was crystallizable from 0.5 saturated ammonium sulfate at pH 5.5, but attempts to crystallize at pH 4.0 (where g-chymotrypsin crystallizes nicely) have met with failure. After 3 recrystallizations the yield of oxidized enzyme was 35%. The proteolytic pH optimum of the recrystallized product was identical with that of α -chymotrypsin, but the optimum for tyrosine ethyl ester hydrolysis was changed by oxidation from pH 6.25 to 6.60. When compared at

the respective optima, the specific esterase activity of oxidized enzyme was 80% and the protease 45% of the original. Acetylation of α -chymotrypsin gave a product with activities very similar to the oxidized material, suggesting that the removal or blocking of an amino group may be a factor.

Competitive inhibition between certain salicylates and pantothenic and pantoic acids for *E. coli*
B. CONNOR JOHNSON AND ELLA M. COHN * *Division of Animal Nutrition, Univ. of Illinois, Urbana*

Twelve different compounds were studied as to their inhibiting effect on the growth of 4 strains of *E. coli*. Of the compounds studied, only salicylic acid and its derivatives acetyl salicylic acid and phenyl salicylate completely inhibited growth at low concentrations (approx. 5 μ M). This inhibition was completely reversed by calcium pantothenate or equally well by pantoic acid but was not reversed by β -alanine, p-aminobenzoic acid, methionine, glutamic acid, lysine or valine. Mandelic acid (in contrast to the report of PERAULT AND GRIFIN *Compt. rend. Soc. de biol.* 138: 506, 1944), cinnamic acid, benzoic acid, m- and p-hydroxy benzoic acids, anthranilic acid and gallic acid gave growth inhibition only at much higher concentrations, and this inhibition was not reversed by pantothenic acid or pantoic acid. The only diphenyl hydroxy acid tested, malic acid, was found to stimulate rather than inhibit growth of *E. coli* on the simple medium used. Salicylic acid, bismuth salicylate and phenyl salicylate have been fed to rats at 0.1 to 1% of pantothenic acid-free diets in attempts to inhibit coliform synthesis of pantothenic acid in the intestinal tract. Under some of these conditions a severe deficiency was produced which was completely counteracted by pantothenic acid.

Distribution of free amino acids between erythrocytes and plasma in normal human subjects
C. A. JOHNSON* AND OLAF BERGEIM *Dept. of Biological Chemistry, Univ. of Illinois, College of Medicine, Chicago*

The plasma and red cell levels of 12 amino acids were determined on single blood samples obtained from 24 young men in a postabsorptive state. Clotting was prevented by heparin and the cell volume measured by hematocrit. Following centrifugation the plasma was siphoned off, the white cell layer removed and discarded, and the red cells hemolysed. The plasma and red cell fractions were then deproteinized with tungstic acid. Microbiological assays of the tungstic acid filtrates were carried out. The results indicated that the concentrations (expressed in γ /ml. of plasma or red cells) of methionine, phenylalanine, threonine and tyrosine were approximately the same in both blood fractions. For the remaining amino acids, the

ratios of the concentrations in plasma to the concentrations in red cells increased in the following order: leucine, histidine, valine, lysine, isoleucine, cystine, tryptophane and arginine, the ratios ranging from 1.2 for leucine to 6.2 for arginine. If the individual amino acid concentrations were calculated on the basis of red cell water (65%) and plasma water (92%), the 12 amino acids studied might be arranged in three groups: 1) those with cell levels above plasma levels, 2) those about equally distributed, and 3) those with cell levels below plasma levels. It would appear, therefore, that red cells may show some selectivity in regulating the passage and accumulation of these amino acids.

Mode of action of the sperm 'regulator,' 2,4-dinitrophenol and usnic acid
R. BERNAL JOHNSON,* AND HENRY A. LARDY *Dept. of Biochemistry, Univ. of Wisconsin, College of Agriculture, Madison*

In studies of the function of a naturally occurring metabolic 'regulator' (*Science* 109: 365, 1949) it was found that, like dinitrophenol and usnic acid, this substance prevents the phosphorylation reactions normally associated with substrate oxidation by a washed residue of rabbit kidney or rat liver homogenate. In the absence of such 'uncoupling' agents, the oxidation of either carbohydrate or fatty acids (JOHNSON AND LARDY *J. Biol. Chem.* in press) is accompanied by a net uptake of inorganic orthophosphate. With either citrate, *cis*-aconitate, α -ketoglutarate, succinate, malate, fumarate, or pyruvate plus a trace of fumarate as the substrate, about 15 μ M of phosphate is taken up in 10 minutes and transferred to glucose by means of yeast hexokinase. In the presence of suitable concentrations of either the sperm 'regulator,' dinitrophenol or usnic acid, uptake of phosphate occurs but it accumulates in the form of an extremely acid-labile compound. This unidentified ester (not inorganic pyrophosphate or metaphosphate) is reasonably stable at pH 4. At this pH its hydrolysis is catalyzed by molybdate. Under some conditions the labile ester accumulates even in the absence of the 'uncoupling' agents indicating that it may be a naturally occurring intermediate.

Synthesis of glutathione in extracts of pigeon liver
ROBERT B. JOHNSTON* AND KONRAD BLOCH *Dept. of Biochemistry and Inst. of Radiobiology and Biophysics, Univ. of Chicago, Chicago, Ill.*

The formation of the peptide bond between cysteine and glycine in glutathione has been investigated with the aid of C^{14} -glycine. A dialyzed saline-bicarbonate extract of acetone-dried pigeon liver was the source of the enzyme. Peptide bond formation, as measured by the incorporation of labeled glycine into glutathione, occurs in such extracts at a rapid rate when glutamic acid, cysteine,

glycine, Mg^{++} , phosphate, and either adenosine triphosphate or 5-adenylic acid are added Under these conditions ATP and 5-adenylic acid are equally effective, while inosinic acid and guanylic acid show a much smaller effect The isolated glutathione contains no significant radioactivity when the adenylic acid derivatives are absent or when Mg^{++} or phosphate are omitted Under the same experimental conditions peptide synthesis can also be effected by the addition of various amides In the presence of enzyme, amino acids and salts, the following amides caused the formation of C^{14} glutathione glutamine, asparagine, pyruvamide, and acetamide In these experiments also the presence of phosphate is necessary These results suggest that the energy of the amide bond can be utilized for peptide synthesis

In vitro effect of DDT and its metabolites on rat heart succinoxidase CARTER D JOHNSTON (introduced by R LORIMER GRANT) *Division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D C*

DDT, its dehydrochloride, and its acetic acid derivative (DDA) were added to rat heart homogenates suspended in phosphate buffer (pH 7.4), using succinate as the substrate Oxygen consumption was measured manometrically DDT inhibited this succinoxidase system 60% at a concentration of 10^{-4} M, while DDA (an important metabolite of the insecticide) caused only 33% inhibition at 5 times this concentration The dehydrochloride, possibly a metabolic intermediate, is as effective as DDT in suppressing the oxygen uptake of these preparations

Effect of desoxycorticosterone glucoside (DCG) on glucose reabsorption in the dog kidney

EDWIN H KAUFMAN AND AGAMENON DESPOPOULOS (introduced by DONALD D VAN SLYKE) *Hospital of Rockefeller Inst for Med Research, New York City*

St Rusznyak *et al* (*Experientia* 3:420, 1947) reported that intravenous DCG (Percorten Glucoside, Ciba) in barbiturate-anesthetized dogs produced a several-fold increase in Glucose Tm The present study, in which TmG was measured before and after i.v. injection of DCG in dogs under pentobarbital anesthesia, was an attempt to confirm this remarkable observation Our results showed, on the contrary, a prompt depression of TmG following single doses of 30-100 mg in dogs weighing 13-25 kg, with TmG decreasing to zero after the 100 mg dose The inhibition persisted 30 minutes after 30 mg, and longer with larger doses Reduction of 25% of control TmG was maintained by constant i.v. infusion of 1 mg/min Marked glycosuria, with no change from normal in blood glucose concentration, following injection of 150 mg of DCG in a dog receiving no exogenous glu-

cose DCG had no consistent effect on glomerular filtration rate These results are in agreement with those recently published by Lambert and associates (*Acta Clin Belgica* 3:529, 1948) showing that DCG depresses TmG in man The failure of 30 and 60 mg i.v. doses of free desoxycorticosterone in propylene glycol to decrease TmG below levels produced by control injections of the vehicle alone, indicates that the depressant action on the glucose reabsorptive mechanism is a property of the glucoside rather than the free steroid That this action may be analogous to that of phlorizin is suggested by certain structural similarities between the two molecules

Anticoagulant polysaccharide sulfates LOUIS A KAZAL, DANIEL S SPICER* AND ROSE A BRAHINSKY* *Dept of Biochemistry, Med Research Division, Sharp and Dohme, Inc, Glenolden, Pa*

A number of polysaccharides were sulfated with pyridine chlorosulfonic acid (P.C.A.) (2.5 hours at 75-80°C), and the sulfated products screened for anticoagulant activity by a modification of the prothrombin time determination Chlorosulfonic acid and concentrated sulfuric acid also were employed as sulfating agents in some instances The sulfated products obtained with P.C.A. were more active as anticoagulants than those obtained with the other agents The most active products were derived from dextrin, karaya gum, tragacanth, chitin, sodium ammonium pectate, cellulose and oxidized cellulose Dextrin was selected for more detailed studies, it was sulfated under various conditions of time and temperature, and the resultant products tested for anticoagulant activity and for toxicity in rabbits Essentially maximum activity was reached in 2 to 1 hour periods of sulfation at 60°C and 102°C, and in 3 hours at 45°C At a constant temperature of sulfation, less toxic products were obtained with short periods of sulfation, with time a constant, less toxic products were obtained at lower temperatures of sulfation Using constant conditions for sulfation (1 hour, 60°C) the products derived from low ml wt dextrans were more active The glycolic acid ether of dextrin sulfate was slightly less active than the parent substance The dextrin sulfates have an *in vivo* activity in the rabbit approximately equivalent to $\frac{1}{2}$ of that of heparin (Connaught Standard)

Reversible changes in the L-amino acid oxidase molecule EDNA B KEARNEY* AND THOMAS P SINGER *Dept of Biochemistry, Western Reserve Univ School of Medicine, Cleveland, Ohio*

We have reported (*Federation Proc* 8 no 1) that the oxidase of many snake venoms is inactivated by low concentrations of $PO_4^{=}$ and related ions It has been found that in distilled water the enzyme is inactivated similarly because of protein-bound

PO_4^{2-} and that at higher temperatures an opposing process of reactivation occurs. An equilibrium therefore exists between the active and inactive forms of the enzyme characteristic of the temperature and pH, at 45°C (pH 7) the equilibrium is largely in favor of the active form, and at 30° , the inactive form. The temperature determines both the position of the equilibrium and the rate at which it is reached. Monovalent anions prevent the inactivation and enhance reversal, incubation with Cl^- at 38° completely reactivates the inactive enzyme. PO_4^{2-} increases the rate of inactivation and shifts the equilibrium toward the inactive form. Following inactivation by PO_4^{2-} , heating with Cl^- effects reactivation only after the excess PO_4^{2-} is removed by dialysis. While PO_4^{2-} is rapidly bound by the protein even at 0°C , the inactivation occurs only gradually on incubation at higher temperatures, indicating a secondary process with an appreciable activation energy. This process is not a polymerization or denaturation, as the inactive enzyme retains the size and shape of the active form, as judged by ultracentrifuge studies. The mechanism of the inactivation may involve an intramolecular bridge formation between PO_4^{2-} and a protein group, possibly histidine. The nature of the bond is being studied with the aid of P^{32} .

Inhibition of rat liver choline oxidase by urethane
in vitro CECILIA K. KEITH AND JAMES S. DINNING (introduced by PAUL L. DAY) *Dept. of Biochemistry, Univ. of Arkansas School of Medicine, Little Rock*

Choline oxidase was determined by standard Warburg procedure. The final volume in the flasks was 3.2 ml containing 1 ml of a 5% rat liver homogenate buffered at pH 7.8. With 5 mg of choline chloride added as substrate, 5, 10, 50, and 100 mg of urethane inhibited choline oxidase 4, 27, 78, and 84% respectively. With 50 mg of urethane the addition of 5, 10, 15, 20 and 25 mg of choline chloride resulted in the consumption of 24, 30, 38, 33, and 28 μl O_2/hr respectively. The tissue preparation with 25 mg of choline chloride as substrate and no urethane consumed 98.6 μl O_2/hr . It appears that the inhibition of choline oxidase produced by 50 mg of urethane is not readily reversible by increasing the amount of substrate. Urethane was without effect on the succinic oxidase activity of these tissue preparations. This inhibition of choline oxidase by urethane is of interest in view of the fact that the nitrogen mustards and aminopterin, also substances which reduce white cell counts in animals, inhibit choline oxidase.

Lipotropic effect of pteroylglutamic acid on rats receiving toxic levels of dietary glycine BARBARA KELLEY* AND JOHN R. TOTTER *Dept. of Biochemistry, Univ. of Arkansas School of Medicine, Little Rock*

Weanling littermate Sprague-Dawley rats were placed on an adequate purified diet containing 10% glycine with and without added pteroylglutamic acid (PGA). Another group of animals received the diet without added glycine (basal diet). Liver fats were determined on all of the animals after 54–60 days on the various diets. The addition of 10% glycine to the diets brought about a 50% increase in the fat content of the liver over that on the basal diet. When PGA was added to the high glycine diet at a level of 5 mg/kg the liver fat was reduced to a value slightly lower than that obtained on the basal diet. In one experiment the average values for liver fatty acids of 10 animals were as follows: 10% glycine diet, 5.68%, 10% glycine + PGA, 3.70%, and basal diet 3.92%. The possibility that the observed increase in liver fats on the high glycine diet is due to a metabolic deficiency of choline is suggested by an elevated kidney weight/body weight ratio, which was also reduced to normal by PGA.

An automatic multiple extraction apparatus

MARIAN W. KIES AND PAUL L. DAVIS * *Bureau of Agricultural and Industrial Chemistry, Agricultural Research Center, Beltsville, Md*

Recent work on countercurrent distribution has emphasized its usefulness in biochemical fractionations, but the available equipment is inadequate for large-scale work, and repeated extractions in separatory funnels are much too laborious. An apparatus has been devised in which large volumes of solvent can be handled with little effort. Its principle differs somewhat from that of the Craig machine, but the end result—separation of solutes having different distribution coefficients—is similar. Successive aliquots of the quiescent (heavier) phase of two immiscible solvents are subjected to continuous extraction by extremely small increments of the lighter phase. The apparatus consists of a series of side-arm test tubes, each containing a separate inner tube having a coarse fritted disk sealed to the lower end. The solute is placed in the first test tube, after which all the tubes are filled with the heavier member of a solvent pair. The lighter member is then introduced continuously and at a properly regulated rate into the first dispersion tube. Droplets of upper phase enter the lower phase through the fritted disk, rise to the top and overflow into the next dispersion tube. The number of tubes necessary, as well as the total volume of upper phase required for any degree of separation of two or more solutes can be predicted from their respective distribution coefficients. The versatility of the apparatus and the ease with which it can be assembled and used suggest a wide application for it in fractionation studies.

Hydrolysis of glutathione J R KIMMEL,* C K OLSON,* DONALD OKESON* AND FRANCIS BINKLEY *Univ of Utah College of Medicine, Salt Lake City*

The enzyme of pig kidney responsible for the hydrolysis of glutathione to glutamic acid and cysteinylglycine has been separated from the enzyme responsible for the hydrolysis of cysteinylglycine. The activity is associated with a lipoprotein of high molecular weight. Considerable activation of all preparations is obtained by the addition of glutamine, the preparations of highest purity are relatively inactive in the absence of glutamine. The hydrolysis of glutathione is inhibited in a competitive manner by various phthaleins and by penicillin G, these inhibitions may be reversed by the addition of either glutamine or glutathione. The antibacterial action of penicillin toward *S aureus* is reversed under certain conditions by glutamine and/or glutathione.

Enzymatic hydrolysis of urinary reducing lipids

RALPH A KINSELLA, JR, R J DOISY AND JOHN H GLICK, JR (introduced by EDWARD A DOISY) *Dept of Biological Chemistry, Saint Louis Univ School of Medicine, Saint Louis, Mo*

Enzymatic hydrolysis of urinary neutral reducing lipids has yielded increases in reducing activity of 3-5 times that of suitable controls. The order of increase is the same for normal male and for pregnancy urine. In terms of the reducing power of desoxycorticosterone, values ranging from 8 to 30 mg/24 hr for normal male urine and 24-41 mg/24 hr for pregnancy (9th month) urine have been obtained. The enzyme source is the culture fluid preparation of Buehler, Katzman and Doisy (*Federation Proc* 8:189, 1949) which is obtained by centrifugation (to remove cells and menthol) of a 10-day old culture of a strain of *B coli*, which was grown in the presence of menthol glucuronide, and is rich in glucuronidase. Five or 10 ml of urine is mixed with one ml of culture fluid, the pH adjusted to 6.2 ± 0.1 with 0.6 M phosphate, and the mixture incubated at 38° over chloroform for 15-18 hours (overnight). The mixture is brought to pH 1 with 12 N H₂SO₄ and extracted 4 times with 2 volumes of ether chloroform (4:1), the extract is washed with 0.1 N NaOH and water, dried with Na₂SO₄, transferred to an Erlenmeyer flask and evaporated with a water pump at a temperature not over 35°C. The reducing power is then determined directly on the residue, using 3 ml of the phosphomolybdate reagent of Heard, Sobel and Venning (*J Biol Chem* 165:699, 1946) for color development and 7 ml for dilution.

Effect of beryllium on certain enzymes FRIEDRICH W KLEMPERER *Dept of Biochemistry of Trudeau Fdn for Clinical and Experimental Study of Pulmonary Disease, Trudeau, N Y*

The effect of beryllium on tissue slices and various enzymes has been investigated. Previously it had been reported by us that alkaline phosphatase was partly inhibited by concentrations of beryllium lower than 10^{-6} M. Acid phosphatase was slightly inhibited by 10^{-3} M Be. DuBois *et al* have demonstrated an effect of 0.8×10^{-3} M Be on adenosine triphosphatase (*Science* 110:420, 1949). Respiration of rat liver slices was unaltered by 10^{-3} M Be. Succinic oxidase activity of liver-homogenate was enhanced by beryllium ions while succinic dehydrogenase was unaffected. The mechanism of this activation appears similar to that described for aluminum. Beryllium in concentrations up to 10^{-3} M had no effect on glycolysis induced by acetone powder of muscle. Aldolase, isomerase, carboxylase, and arginase were not inhibited by beryllium and the divalent metals which normally activate these enzymes could not be replaced by beryllium. Uricase and carbonic anhydrase were also unaffected by beryllium.

Electrophoretic studies of plasma proteins in children with rheumatic fever ELIZABETH L KNAPP,* ROBERT L JACKSON* AND JOSEPH I ROUTH *Depts of Pediatrics and Biochemistry, State Univ of Iowa College of Medicine, Iowa City*

Electrophoretic analysis has been made of over 200 plasma samples from 70 children with rheumatic fever in different stages of the disease. Serial studies on many children are included. Plasma samples were diluted and dialyzed with veronal buffer, pH 8.6, for 3 days in the cold. Electrophoresis was conducted at 0-8°C in the Longworth modification of the Tiselius apparatus. During the more active phase of the disease the values for plasma albumin were consistently and markedly decreased but increased with clinical improvement. Increases in the α -globulins frequently were observed in children with exudative manifestations of the disease. Marked increases in both fibrinogen and γ -globulin often were noted during the early acute phase, although a given child might not show deviations in both fractions. The γ -globulin fraction usually returns to normal more slowly than the other components, the rate of return appears to follow the rate of clinical improvement. Statistical analysis indicated a significant association between changes in sedimentation rate and changes in albumin, fibrinogen and γ -globulin. Examination of serum samples in this disease indicates that the γ -globulin component is normal. For this reason the elevation in the fibrinogen fraction would appear to be real and not an artefact. These biochemical data are being studied further in relation to the clinical and nutritional status of the child, duration of the disease, amount of residual cardiac damage, and also as a laboratory guide to determine inactivity of the disease process.

Effect of adrenal cortical steroids on arginase activity CHARLES D KOCHAKIAN AND EVANGELINE ROBERTSON * *Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*

The subcutaneous injection of aqueous adrenal cortical extract (Upjohn) at 8×0.25 ml/hr and 11-dehydrocorticosterone acetate (Merck) at 8×0.25 mg/hr into fasted castrated adult mice did not alter the arginase activities of the liver or kidneys but did increase the liver glycogen and urinary nitrogen excretion. On the other hand, a subcutaneously implanted 13-15 mg pellet of 11-dehydro-17-hydroxycorticosterone acetate produced a significant increase in both the liver and kidney arginase activities after 2 days. On extending the treatment a further increase was attained after 7 and 30 days. The same increases were obtained when the enzyme was determined with CoCl_2 as the enzyme activator or by preactivation at 50°C with mm Cl_2 . The body weight of these treated mice decreased very sharply during the first 4-6 days accompanied by an increased nitrogen excretion, a nearly complete disappearance of the thymus within 2 days and a decrease in the size of the spleen. The liver increased in weight after 2 days but, thereafter, progressively decreased. The kidney showed no change after 2 days but was significantly increased after 7 and 30 days. 11-dehydrocorticosterone (Kendall) implanted as a pellet for 7 and 30 days produced effects qualitatively similar but quantitatively less than those of 11-dehydro-17-hydroxycorticosterone acetate. The injection of 11-dehydrocorticosterone acetate (Merck) in oil solution at 0.5 mg/day for 26 days was completely ineffective.

Fractionation of blood lipides in organic solvents at low temperature ALFRED E KOEHLER AND ELSIE HILL * *Sansum Clinic Research Fndn and Santa Barbara Cottage Hospital, Santa Barbara, Calif*

An apparatus has been devised consisting of two 50 cc Erlenmeyer flasks joined at their opening to a glass fritted disk. Side arm connections to the bottom of the flasks permit filling and emptying and equalization of pressure. A group of these vessels are rotated on an axis at their center so as to permit agitation and inversion for filtering. A solution containing 2-4 mg of lipides in petroleum ether is evaporated in the bottom flask and 10 cc solvent added. The vessel is stoppered to prevent evaporation or the access of moisture. After 24 hours of shaking at low temperature the apparatus is inverted for gravity filtering without any disturbance of the temperature. A useful temperature has been found to be -26° particularly so that an ordinary freezing cabinet can be adapted. In ethanol the esters of the saturated fatty acids of cholesterol are insoluble, with the exception of the butyrate but the latter has not been found in the blood lipides. Free cholesterol and neutral fats in

equivalent amounts are soluble and can be thus separated. The unsaturated fatty acid esters are soluble, particularly linoleic which constitutes about 62% of the cholesterol esters. In methanol a separation of the cholesterol esters from neutral fat can be made inasmuch as the esters are nearly completely insoluble. This permits separation of the cholesterol esters so as to enable a study of their constitution.

Failure of pterylglutamic acid (PGA) to function as growth factor for *L. arabinosus* (17-5) BERNARD W KOFT,* E STEERS* AND M G SEVAG *Dept of Bacteriology, Univ of Pennsylvania School of Medicine, Philadelphia*

It has been found that it is a decomposition product and not PGA *per se* which is a growth stimulant for *L. arabinosus*. Growth stimulation by PGA is directly related to the degree of decomposition. Aged PGA (80% decomposed, calculated as p-aminobenzoylglutamic acid (PABG)) is almost 100-fold more active than intact PGA, as are also p-aminobenzoic acid (PABA) and PABG. In systems containing 3% phosphate ($\text{pH } 6.8$) to maintain neutrality, unlike PABA, PABG and aged PGA, intact PGA fails to stimulate growth earlier than after 72 hours. The antagonism of PGA *per se* to sulfonamides here is apparent rather than real, and is controlled by the following: 1) an incubation period which is associated with the decomposition of PGA and is necessary for any antagonism to sulfonamides, 2) the concentration of PABG and/or PABA which brings about a competitive type of antagonism, PABG content of 0.01 γ of PGA, though adequate for optimal growth, is inadequate to antagonize 1 γ of sulfonamide, and 3) the rapid increment of acidity in the medium. The increased acidity suppresses the inhibitory capacity of sulfonamide and augments the anti-sulfonamide capacity of the liberated PABG. In a well-buffered medium containing 3.0 gm % of phosphate ($\text{pH } 6.8$) the complete inhibition of growth by sulfonamides persists in the presence of PGA without a detectable reversal. These data do not support the postulate (*J Biol Chem* 170:133, 1947) that sulfonamides interfere with the synthesis of PGA via PABA or PABG.

Permeability of axonal surface membranes to amino acids SAUL R KOREY (introduced by H T CLARKE) *Dept of Neurology, Columbia Univ College of Physicians and Surgeons, New York City*

The changes of permeability of axonal surface membranes are an essential element in the conduction of nerve impulses. The availability of stable and radioactive isotopes has provided the possibility of approaching the problem of the properties affecting the permeability of cell membranes. For the study of the permeability of axonal surface membranes the giant axon of Squid has proved to

be an excellent material in this connection. Studies were initiated with amino acids labeled with N^{15} . Giant axons of Squid were exposed to artificial sea water prepared according to Pantin in which 0.1 M of NaCl was replaced by the labeled amino acid in the same concentration. After 30 minutes exposure the axoplasm was extruded and the atom percentage excess N^{15} determined after the usual preparation. In the cases in which glycine containing 32 atom % excess N^{15} , alanine containing 23 atom % excess N^{15} and L-aspartic acid containing 30 atom % excess N^{15} were used, the following data may be considered typical. After 30 minutes exposure to glycine 0.949 and 1.10 atom % excess N^{15} were found in the axoplasm. This corresponds to 15.3 and 17.7 μM of N/gm. Since the outside solution contains 100 μM of N/ml, 16.5% had penetrated within the period of exposure. In the case of alanine 0.4307 atom % excess N^{15} were found, corresponding to 9.7 μM /gm. After exposure to L-aspartic acid 0.276 atom % excess N^{15} were found, corresponding to 4.7 μM /ml.

Isocitric acid breakdown in yeast ARTHUR KORNBERG *Natl Insts of Health, Bethesda, Md*

With triphosphopyridine nucleotide (TPN) as a specific coenzyme and acetone powders of animal tissues, Adler *et al* (*Biochem J* 33: 1028, 1939) demonstrated the oxidative decarboxylation of isocitric acid to α -ketoglutaric acid and CO_2 . Ochoa (*J Biol Chem* 174: 115, 1948) provided evidence for oxalosuccinic acid (OSA) as the intermediate and established the reversibility of the reaction starting either with α -ketoglutaric acid and CO_2 or with OSA. Our studies with extracts of either fresh baker's or dried brewer's yeast indicate the existence of 2 distinct and readily separable systems for isocitric acid breakdown. One is TPN-specific and the other diphosphopyridine nucleotide (DPN)-specific. The TPN system is entirely comparable with that of Ochoa. The DPN system, which has been purified over 50-fold, has certain distinctive features. Although this enzyme catalyzes the stoichiometric conversion of D-isocitric acid to α -ketoglutaric acid (identified by chemical and enzymatic means), it does not catalyze either the fixation of CO_2 in α -ketoglutaric acid or the reduction of OSA. Also, in addition to a strict specificity for DPN, it requires the presence of adenosine-5-phosphate in catalytic amounts and is inhibited by sodium azide.

Sources of bacteriophage nitrogen LLOYD M KOZLOFF*, KATHRYN KNOWLTON*, FRANK W PUTNAM AND E A EVANS, JR *Dept of Biochemistry, Univ of Chicago, Chicago, Ill*

The precursors of the nitrogenous components of *Escherichia coli* bacteriophage T r^{+} were studied using both N^{15} labeled bacterial cells and medium. While the medium is the source of about

80% of the virus N, bacterial N also appears in both phage nucleic acid and protein. The major portion of the bacterial N contribution was found in the virus nucleic acid. Sixteen-43% of the virus nucleic acid was derived from the host. The N of the purine and pyrimidine bases contained about equal proportions of host N. When the bacteria were labeled with N^{15} and P^{32} the ratio of $\frac{\% \text{ of virus nucleic acid N from host}}{\% \text{ of virus nucleic acid P from host}}$ was 1.3-1.4.

The amount of bacterial N appearing in the virus nucleic acid was found to be independent of the time of lysis or the number of virus particles produced/cell. These results indicate that bacterial desoxyribonucleic acid is utilized for the synthesis of the new virus particles. Seventy-five to 95% of phage protein N came from the medium after infection of the host while the remaining 5-25% was contributed by the host. The bacterial N contribution was distributed among the various amino acids of the virus. The actual amount of bacterial N appearing in the phage protein was inversely proportional to the number of virus particles produced/bacterial cell.

Cytosine deaminase of yeast JACOB KREAM* AND ERWIN CHARGAFF *Dept of Biochemistry, Columbia Univ, College of Physicians and Surgeons, New York City*

The discovery of an enzyme in cell-free extracts of bakers' yeast which deaminates cytosine to uracil (CHARGAFF AND KREAM *J Biol Chem* 175: 993, 1948, compare also HAHN AND LINTZEL *Ztschr Biol* 79: 179, 1923) prompted a study of its preparation and properties. A 5-fold concentration of activity in terms of protein was effected when the enzyme was precipitated from the supernatant, resulting from the centrifugation at 15,000 g of aqueous extracts of crushed cells, by adjustment to between 0.25 and 0.7 saturation with $(NH_4)_2SO_4$. Following the evaporation of the dialyzed frozen solutions in a vacuum, preparations stable for a long period when stored in the dry state at -15° were obtained. The kinetics of the enzymatic reaction were studied by means of the previously published analytical methods (VISCHER AND CHARGAFF *J Biol Chem* 176: 703, 1948). The pH optimum was found at pH 6.8-6.9, the temperature optimum lay between 34° and 37.5° (dependent upon the duration of incubation). The enzyme solutions were very sensitive to heat. Considerable inactivation at 37.5° was prevented by the substrate cytosine and to a less extent by uracil. The preparations contained neither guanase nor adenase. Conclusions as to the structural specificity of the enzyme can be drawn from the fact that it does not deaminate cytidine, cytidylic acid, thiocytosine, 2-methoxy cytosine, 5 amino uracil, or isocytosine which latter acts, in fact,

as an inhibitor 5-Methyl cytosine, however, is deaminated to thymine

Estimation of lipoproteins in serum immunologically H G KUNKEL (introduced by STANFORD MOORE) *Hospital of Rockefeller Inst for Med Research, New York City*

In order to determine whether the protein moiety of serum lipoproteins was immunologically specific from the other serum proteins and whether elevation of serum lipids causes a rise in such protein, various lipoproteins were purified from normal and pathological sera. Dilution of serum 30 times with a weak buffer solution (pH , 6.4, μ , 0.02) containing 0.005% zephiran chloride has been found to precipitate selectively the lipoproteins from serum. Analysis of such precipitates indicated a lipid content ranging from 50–70%. Further separation of this material by high speed centrifugation in solutions of high density yielded chiefly a clear lipoprotein preparation that by electrophoretic analysis showed one major β globulin component making up 90% of the total area. Injection of this material into rabbits readily produced an antiserum which did not react with purified preparations of albumin or γ globulin although it was very reactive with lipoprotein preparations or whole serum. Similar results were obtained with antisera to the protein portion of the lipoprotein after 90% of the lipid had been removed. Quantitative analysis of precipitin nitrogen indicated that normal serum contained an average of 0.03 gm of lipoprotein nitrogen/100 cc. The majority of sera containing elevated total lipid showed a high content of lipoprotein and sera containing very little lipid were very low in lipoprotein. The values showed a fourfold range of variation. Observations on sera from patients with nephrosis with high serum lipid levels indicated that this normal lipoprotein was markedly increased although the total protein, albumin and γ globulin were very low.

Effect of zinc on oxidation of citric acid cycle intermediates H O KUNKEL (introduced by JAMES B SUMNER) *Dept of Biochemistry and Nutrition, Cornell Univ, Ithaca, N Y*

Copper ions have been shown by Ackermann and Potter (*Proc Soc Exper Biol & Med*, 72, 1, 1949) to inhibit rat liver and kidney succinioxidase systems by forming an inactive non-dissociable complex with the enzyme. I find that zinc ions behave in a similar manner but show more toxicity than copper ions. Under conditions which favor oxidative phosphorylation (isotonic KCl homogenates, Mg^{++} and adenosine-5 phosphate), inhibition by zinc occurs, but this inhibition is transitory. The rate of oxidation subsequently rises to a level even higher than the control data. A later fall to a lower level of activity can be attributed

to the zinc inhibition of the oxidation of other citric acid cycle intermediates, particularly the oxidation of citrate. With the exception of succinioxidase, the oxidizing enzymes of rat kidney are more readily inhibited by zinc ions than are those of rat liver. The addition of a protein such as insulin has no protective action against zinc inhibition, but crystalline zinc insulin causes the same inhibition as does zinc sulfate. Amorphous insulin, in itself, inhibits citrate oxidation by rat kidney homogenates.

Considerations on indiscriminate use of the Waring Blendor: copper contamination and ascorbic acid loss MERTON P LAMDEN (introduced by HAROLD B PIERCE) *Dept of Biochemistry, Univ of Vermont College of Medicine, Burlington*

The Waring Blendor, a useful and popular comminuting apparatus, has been considered undesirable for use in the determination of ascorbic acid since it incorporates large amounts of oxygen into the slurry presumably thus causing oxidative loss of ascorbic acid. Also the Waring Blendor has been shown to cause oxidation of sulfhydryl groups and inactivate enzyme systems. In some instances such untoward effects could be due to the use of containers having blending assemblies with worn chrome plate and an exposed brass undersurface. That dissolved copper, probably originating in the brass, is responsible for the destruction of ascorbic acid in a blended solution was shown in the following manner: 200 ml portions of a solution of ascorbic acid (20 μ g/ml) in 5% metaphosphoric acid were blended for 3 minutes in triplicate in each of 6 Blendor containers. Copper and ascorbic acid were determined in all solutions before and after blending. The coefficient of correlation between the concentration of dissolved copper and the percentage ascorbic acid lost was 0.97. Furthermore, the extent of loss of ascorbic acid correlates rather well with the physical appearance of the blending assembly. Solutions in contact with well plated blending assemblies showed small losses in ascorbic acid, while those solutions in contact with blending assemblies having worn plating or exposed brass parts showed considerably higher losses. The Waring Blendor thus does not contribute to the oxidative loss of ascorbic acid in 5% metaphosphoric acid solution unless copper is dissolved from parts of the blending assembly having worn chrome plate.

Effect of reducing agents on the biological activities of crystalline vitamin B₁₂ CALVIN A LANG* AND BACON F CHOW *Dept of Biochemistry, School of Hygiene and Public Health of Johns Hopkins Univ, Baltimore, Md*

It was reported that reaction of crystalline vita-

min B_{12} with hydrogen in the presence of platinum catalyst with yield vitamin B_{12} , which possesses a lower microbiological activity and animal protein factor activity than vitamin B_{12} . This treatment may involve the addition of hydrogen atoms to double bonds in the molecule or reduction. Our study deals with the reaction between crystalline vitamin B_{12} and several reducing agents (ascorbic acid, cysteine HCl, thiamine HCl, and hydroquinone) in a phosphate buffer at pH 7.6. To this end, a solution of crystalline vitamin B_{12} was mixed with a solution of one of the above mentioned reducing agents, so that the ratio of B_{12} to reducing agent varied from 1:400–1:4000 by weight in several experiments. An aliquot solution of B_{12} to which no reducing agent was added served as the control. These solutions were sealed in pyrex tubes and kept at 37° C for different lengths of time, and changes in spectrophotometric transmittance at 550 m μ were followed. After incubation for a desired interval of time the tubes were opened, and the contents were assayed for excess reducing agent, for microbiological activity using *L. leichmanii*, and for animal protein activity using B_{12} deficient rats. No special precautions were used to exclude air from contact with the solutions. The results obtained demonstrated that the original vitamin B_{12} activities were greatly decreased as a result of incubation in the presence of the reducing agents listed above, whereas the vitamin B_{12} activities of the control tube treated under identical conditions were unaffected.

Radioactive tobacco mosaic virus ROBERT V LASHBROOK* AND HUBERT S LORING *Dept of Chemistry and School of Medicine, Stanford Univ, Stanford, Calif*

Several methods were studied for incorporating radioactive phosphorus (P^{32}) into tobacco mosaic virus in Turkish tobacco plants. The most highly radioactive virus was obtained when normal plants were allowed to take up the P^{32} -phosphate as completely as possible from small volumes of distilled water and were grown in nutrient medium for about two weeks after inoculation. When P^{32} -phosphate was introduced into previously infected plants, the isolated virus was only about one-half as radioactive as that from the newly infected plants. In experiments in which radioactive virus was mixed with macerated plants and re-isolated after standing at room temperature for various periods of time, 60–90% of the original virus was recovered with unaltered radioactivity. When radioactive virus was inoculated onto growing leaves, the recovered virus had the same radioactivity as that used for inoculation but the amount recovered was only 10–20% of the original when the plants were worked up 24 hours later.

In these instances over 50% of the radioactivity was found in the supernatants after ultracentrifugation. The results of the several types of experiments performed have suggested a) that there is little, if any, exchange of P^{32} between virus and host, b) that virus becomes associated with insoluble plant components such as chloroplasts after inoculation, and c) that during virus multiplication the original virus phosphate is largely converted to a non-virus form.

Trypsin inhibitor in colostrum M LASKOWSKI, JR * AND M LASKOWSKI *Dept of Biochemistry, Marquette Univ School of Medicine, Milwaukee, Wis*

Human and bovine colostrum were found to contain a compound inhibiting the proteolytic action of trypsin. The inhibitor content was determined according to Kunitz (*J Gen Physiol* 30:291, 1947). In bovine colostrum maximum content of inhibitor occurred on the 1st day after delivery. In human the peak value was reached between the 1st and 3rd day, and then gradually declined till on the 5th day it was impossible to detect. Partial purification of the inhibitor was achieved by 1) the removal of casein at pH 4.6, 2) removal of inactive proteins by 30% saturation with ammonium sulfate, 3) precipitation of inhibitor by 70% saturation at pH 3.0, 4) removal of the inactive protein by 2.5% trichloroacetic acid at 80°C and 5) precipitation with 70% ammonium sulfate. Steps 3, 4, and 5 are identical with the method of Kunitz and Northrop (*J Gen Physiol* 19:991, 1936). It seems, therefore, likely that the properties of the inhibitor from colostrum and from pancreas may be very similar, possibly possibly identical. Partially purified 'fraction 5' inhibits trypsin apparently by forming a stoichiometric compound. It also possesses a strong blood anti-coagulant action. The physiological significance is now only a matter of speculation, but it is believed that the main purpose of the inhibitor is to protect the antibodies of colostrum. Further purification and the physiological role are under investigation.

In vivo effect of toxic dose of P^{32} on phosphorus fractions of rat thymus P S LAVIK, HELEN HARRINGTON AND G W BUCKALOO (introduced by H G Wood) *Atomic Energy Med Research Project, Western Reserve Univ, Cleveland, Ohio*

In studies of the damaging effects of ionizing radiation, we have examined the over-all changes in the phosphorus fractions in the thymus of young adult rats given a single LD₅₀ dose of $Na_2HP^{32}O_4$, i.e., 4.5 μ C P^{32} /gm body weight. Comparable animals receiving 0.1 μ C P^{32} /gm body weight served as controls. Four or more animals from each group were killed at 4 hours,

1, 2, 3, 6, and 8 days after the injection of P^{32} and the thymus tissue was fractionated into the acid-soluble (AS), inorganic (INORG), phospholipid (PL), ribonucleic acid (RNA) plus 'phosphoprotein' (PP), and desoxyribonucleic acid (DNA) fractions. Specific activity measurements (% of P^{32} dose/mg P) showed a reduced uptake of P^{32} in the AS, RNA plus PP, and DNA fractions. This was particularly the case with the DNA and RNA plus PP fractions. There was histological evidence of tissue damage, and a marked loss (62%) in the gland weight occurred during the first 3 days after P^{32} injection. While the total amount of each of the phosphorus fractions decreased rapidly during this same period, the loss of DNA, RNA plus PP, and AS was greater than would be expected from the change in tissue weight. The DNA concentration (mg DNA phosphorus/gm fresh tissue) had decreased 57% by the end of 3 days and thereafter its concentration remained essentially unchanged. Similar, though less marked, changes occurred in the RNA plus PP and AS fractions, whereas the concentration of the PL and INORG fractions changed little if any.

Differential fixation of sulfate by tissues maintained in vitro LAURENCE L. LAYTON (introduced by E. V. McCOLLUM) *Dept. of Biochemistry, Johns Hopkins Univ. School of Hygiene and Public Health, Baltimore, Md.*

Tissues removed from chicks at various stages of embryonic development or after hatching, and maintained 45 hours *in vitro* in media containing S^{35} labeled inorganic sulfate, exhibit different rates of conversion of sulfate ion to insoluble tissue sulfate. It was found that sulfate fixation by heart ventricle reached a maximum of 160% / 100 mg tissue between the 13th and 15th days of incubation, and dropped to 0.37% on the day of hatching. Tissue from the aortic arch exhibited a constant rate of 2.5% / 100 mg wet tissue from the 10th day of incubation to the 44th day after hatching. Fixation by the midsection of the tibia dropped from 33% on the 8th day of incubation to 0.5% on the day of hatching. SO₄²⁻ fixation by cartilage from the proximal tip of the tibia dropped from 38% on the 9th day of incubation to 0.0% for the lateral condyle on the 6th day after hatching. Tissues from 6-day old chickens gave the following values for sulfate ion absorbed (μ g/100 mg wet tissue): tibial red marrow, 0.4; spleen, 1.0; kidney, 1.0; heart ventricle, 0.18; skeletal muscle, 0.1. Tissues from a 12-year old boy gave the following: muscle, 1.2; eosinophilic granuloma of fibula, 1.1; periosteum, 3.6; bone from fibula, 0.5; μ g/100 mg wet tissue. The indications are that sulfate is utilized in tissue formation.

Incorporation of glycine-2-C¹⁴ into proteins and nucleic acids of normal and neoplastic rat tissues G. A. LEPAGE AND CHARLES HEIDELBERGER * *McArdle Memorial Lab., Univ. of Wisconsin, Madison*

Glycine has been demonstrated to be a precursor of nucleic acids and heme in the rat (HEINRICH AND WRIGHT *Federation Proc.* 8: 205, 1949; ALTMAN, *et al.* *J. Biol. Chem.* 176: 319, 1948). No reports are available to compare the incorporation into neoplastic and normal tissues. Glycine-2-C¹⁴ was administered by stomach tube to normal rats and to rats bearing multiple 8-day Flexner-Jobling carcinoma transplants. Animals were killed at 12, 24 and 48 hours. Samples of liver, thymus and tumor were fractionated to obtain the desoxyribonucleic acid, ribonucleic acid and protein from each. Large samples of blood were taken from each animal and purified protoporphyrin-9 methyl ester isolated. There was no significant difference in specific activity of blood porphyrin, liver and thymus DNA, PNA and proteins between normal and tumor-bearing rats. The specific activities of DNA, PNA and protein of tumor were always higher than those of the liver and thymus. Specific activities of the 12-hour samples were highest. In all cases protein activities were higher than those of the nucleic acids. The purine and pyrimidine bases obtained on hydrolysis of the PNA contained C¹⁴. Further degradation studies are in progress.

Presence in wheat germ oil of factors capable of affecting endocrine metabolism I. EZRA LEVIN AND JOHN F. BURNS (introduced by B. CONNOR JOHNSON) *VioBin Labs., Monticello, Ill.*

An androgenic factor in wheat germ oil Androgenic activity has been demonstrated in wheat germ oil (solvent extracted from fresh wheat germ with ethylene dichloride) by three methods. 1) Increase in the weight of the seminal vesicles of the castrate rat. 10 cc subcutaneously every 2nd day for 3 weeks. Average seminal vesicle weight: wheat germ oil group 206.0 mg; control (injected with sesame oil) seminal vesicle 7.1. The colony was maintained on a 'synthetic' diet using glyceryl trilaurate as a fat source. 2) Increase in combs of full-grown capon. 10 cc injections daily for 5 days. Average increase (H + L) 8.7 mm. 3) Increase in weight of comb on 1- to 5-day old chicks. 0.1 cc daily injections for 15 days. Wheat germ oil group: Average comb weight 136 mg; controls (injected with sesame oil), 54.7. **A progestational factor in wheat germ oil** Progestational activity in wheat germ oil (solvent extracted from fresh wheat germ with ethylene dichloride), has been assayed by the Corner-Allen and McPhail methods, showing a 3+ proliferation, when injected with 10 cc wheat germ oil s.c.

daily for 2 days This reaction corresponds to that given by 0.75 mg of progesterone Both bioassays demonstrate the presence in wheat germ oil of a factor capable of eliciting a progestational response in the endometrium of the rabbit Activity is absent in rabbits given α -tocopherol Diminished activity was found in wheat germ oil solvent extracted from *rancid* wheat germ

Survey of serum cholinesterases in a number of mammalian species MILTON GJELHAUG LEVINE, ROBERT E HOYT* AND ANITA A SURAN* *Inst of Experimental Medicine, College of Med Evangelists, Los Angeles, Calif*

The observation published by Mendel and Rudney (*Biochem J* 37 473, 1943) that the cholinesterases found in animal tissues could be separated into 2 types (the specific and non-specific) on the basis of the hydrolysis of 3 substrates, acetyl-choline, benzoylcholine and acetyl-B-methylcholine, led them and other workers to the assumption that all mammalian species had one or the other or both of these cholinesterases They have indicated, for example, that rabbit serum has both forms (*Science* 100 499, 1944) Our work shows that only one cholinesterase is present in the serum of this species (the specific type) and in addition, an enzyme which hydrolyzes benzoylcholine but not acetylcholine A number of other mammalian species have been investigated (rat, guinea pig, dog, monkey, horse, cow, goat, swine) and indicate that there are a whole family of enzymes capable of hydrolyzing acetylcholine, rather than merely the 2 suggested by Mendel and Rudney

Serum proteins and experimental liver damage in the rabbit MILTON GJELHAUG LEVINE, ROBERT E HOYT AND ANITA A SURAN (introduced by R J WINZLER) *Inst of Experimental Medicine, College of Med Evangelists, Los Angeles, Calif*

Liver damage was produced in rabbits by the oral administration of CCl_4 in Wesson oil The animals were fed 1 cc of 20% solution twice weekly for the period of the experiment The progress of the liver damage produced was studied by biopsy and necropsy Serum proteins and serum cholinesterase were determined weekly up to the time of death Of the 23 rabbits studied, 18 developed cirrhosis and were observed for the periods up to 5 months Five of the animals showed fatty degeneration and necrosis of the liver after being killed early in the experiment (2-29 days after CCl_4 administration was started) None of the animals showed a significant decrease in either serum acetylcholine or benzoylcholine hydrolysis during the period of observation The most interesting observation made was that despite obvious liver damage, none of the animals showed a decrease in serum proteins This observation, how-

ever, coincides with that of Kwok-Kew Cheng (*J Path & Bact* 61 23, 1949) in the same animal

Influence of pH upon rates of denaturation of some proteins MILTON LEVY AND ROBERT C WARNER *Dept of Chemistry, New York Univ College of Medicine, New York City*

For many years it has been customary to distinguish between the products of acid denaturation, alkali denaturation and heat denaturation of proteins The processes leading to denaturation have been classified on the same basis Thus heat is regarded as a 'physical' denaturing agent whereas hydrogen and hydroxyl ions are regarded as 'chemical' denaturing agents Nevertheless, it is clear that the intensity factor associated with acidity and alkalinity (the pH) and with heat (the temperature) in aqueous solutions are continuous and not mutually exclusive functions We must regard the rate of denaturation of a protein in solution as a simultaneous function of temperature and pH The temperature function has been handled in terms of the Arrhenius equation or some interpretation of it but the pH function has been dealt with rationally only in limited situations Studies on the rates of denaturation of a number of proteins will be presented which demonstrate that the postulates of Steinhardt (*D Kgl Danske Videnskabers Selskab Math-fysik Med* 14 11, 1937) suitably generalized and modified lead to rational general descriptions of the relation between rate of denaturation and pH From these descriptions one can draw the conclusion that only a very limited number of the hydrogen ion donor and acceptor groups in the protein molecule are significant for its denaturation and, therefore, general salt bridges are relatively minor factors in determining the structure of native proteins

Alterations in steroids excretion after administration of ACTH in man SEYMOUR LIEBERMAN, LUCIE B HARITON* AND KONRAD DOBRINER *Sloan-Kettering Inst for Cancer Research, New York City*

The steroid excretion patterns before, during, and after the administration of ACTH to human subjects have been investigated After the liberation of the urinary steroids from the conjugates by continuous ether extraction at pH 1 without prior heating followed by hydrolysis of the 'glucuronide' fraction with calf spleen β -Glucuronidase, the free steroids were partitioned between benzene and water The constituents of the 'Water Soluble' and 'Benzene Soluble' α and β ketonic fractions have been studied Compound F and a new adrenal metabolite, pregnane $3\alpha,17\alpha,21$ -triol-11,20 dione, isolated as acetate, m p 234-238°, $[\alpha]_D^{25} + 89^\circ$, was isolated from the 'Water Soluble' fraction The latter compound was also detected

in the urine after the administration of Cortisone Acetate. At least 6 other crystalline steroids, as yet unidentified, have been isolated. Androstane-3,17-dione, etiocholan-3,17-dione, androsterone, etiocholanolone, pregnan-3 α -ol-20-one, 11-keto-etiocholanolone, and 11-hydroxyandrosterone, were present in the 'Benzene Soluble' extracts and were excreted in increased amounts during the period of ACTH administration. A number of new unidentified compounds, some of which have been observed previously only in the urine from patients with Cushing's Syndrome, have been detected in this 'Benzene Soluble' fraction. The nature of the new compounds isolated and the variations in the excretion of the individual steroids in relation to steroid metabolism during stimulation of the adrenals by ACTH will be discussed.

Specificity of xanthine oxidase DORIS C. LORZ*
AND G. H. HITCHINGS *Wellcome Research Labs, Tuckahoe, N. Y.*

Fifty purine derivatives and structural analogs of the naturally-occurring purines and 10 pyrimidines have been tested for their ability a) to serve as substrates for xanthine oxidase, b) to inhibit the action of the enzyme on xanthine. Purines in general exhibit more or less ability to combine with the enzyme as measured by the inhibition of xanthine oxidation. A number of unnatural purines and analogs serve as substrates. Thus 8-azaxanthine is oxidized to 8-azaxanthine, 2-amino-purines are oxidized to the corresponding guanines and 2-hydroxypurines are oxidized to 2,8-dihydroxypurines. 1-Methylxanthine is unique in that it is oxidized faster than xanthine. A few pyrimidines have been found to have activity. 4-Hydroxypyrimidine is oxidized to uracil and 4-hydroxy-5-methylpyrimidine is oxidized to thymine, while 4-amino-2,6-dihydroxypyrimidine is an inhibitor. From these data it is possible to determine some of the special requirements for combination of substrate and enzyme and to assess the influence of the nature of certain functional groupings on the course of the enzymatic action.

Inhibition of respiration and acceleration of aerobic glycolysis in tissue slices by certain α,β -unsaturated anions H. J. LOWE,* E. C. WEINBACH,* W. R. FRISSELL* AND LESLIE HELLMAN *Dept. of Physiological Chemistry, Johns Hopkins Univ. School of Medicine, Baltimore, Md.*

Respiration is inhibited markedly with concomitant acceleration of aerobic glycolysis, approaching the anaerobic level, in slices of various organs of the rat and guinea pig. The inhibitors include the cinnamate, benzoate, and related ions. The inhibitor ions are known to embarrass oxidation of amino acids and fatty acids in such tissues.

In our hands, they fail to slow the rate of disappearance of phosphoglycerate, lactate, and pyruvate. They do not affect significantly the rate of oxygen-uptake in the presence of key substrates for the tricarboxylic acid cycle. These agents fail to alter the rate of aerobic glycolysis in certain cultured malignant cells and tumors derived from rat fibroblasts. The phenomenon is interpreted as a 'reversal of the Pasteur effect' initiated by a denial of essential substrates through a competitive mechanism.

Use of partition chromatography for the study of porphyrin metabolism in the rat JOHN LUCAS* AND JAMES M. ORTEN *Dept. of Physiological Chemistry, Wayne Univ. College of Medicine, Detroit, Mich.*

Partition chromatography employing silica gel at a pH of 4.5 and using mixtures of chloroform and ligroin as the mobile phase has been found satisfactory for the separation of small amounts of the various porphyrins occurring in feces and urine. The urine or extracted feces are adsorbed on talc after adjusting to a pH of 4.0 and the methyl esters of the porphyrins are obtained by subsequent treatment with methyl alcohol-hydrogen chloride. The methylated products are dissolved in chloroform, washed, concentrated, and then chromatographed. The various major porphyrins separate as distinct entities on the column. By collecting fractionally and reading the fractions in a spectrophotometer or a photofluorometer previously calibrated with pure crystalline proto-, copro-(I) and uro-(I) porphyrin, respectively, small amounts of these porphyrins may be determined quantitatively. The foregoing procedure is being applied to studies of porphyrin metabolism in the rat. The influence of dietary protein and of glycine on the synthesis of proto-, copro-, and uroporphyrin as indicated by fecal excretion is now under investigation. Five groups of rats are fed the following diets: 1) a purified basal diet, 2) basal diet plus 2% glycine, 3) basal diet plus 3% sodium benzoate, 4) basal diet plus 3% sodium benzoate and 2% glycine, 5) basal diet containing only 3% protein. Feces and urine are collected quantitatively each day and body weights, food intake, and hemoglobin levels are determined weekly. The results indicate a relationship in the rat between the protein and glycine intake, and porphyrin synthesis as measured by fecal porphyrin excretion and hemoglobin formation.

Liver desoxyribonucleoprotein J. MURRAY LUCK, DONALD KUPKE,* ALBERTA RHEIN* AND A. CLARK GRIFFIN* *Dept. of Chemistry, Stanford Univ., Stanford, Calif.*

Desoxyribonucleoprotein has been prepared from the livers of normal rats. Homogenates and

nuclei were used as the source material. Differential extractions with sodium chloride and precipitation in 0.14 M sodium chloride were used in preparation. The product, dialyzed until salt-free, was lyophilized and used for determination of nucleic acid content, free and bound lipid, and protein. The purine and pyrimidine bases of the nucleic acid portion were determined as well as the amino acid distribution in the protein hydrolysate. The lyophilized nucleoprotein does not redissolve satisfactorily either in water or in molar sodium chloride. Other studies in this laboratory confirm the findings of others that dissociation proceeds in solutions of high ionic strength. The low solubility of the nucleoprotein in 0.001 M citrate or arsenate militates against the use of aqueous extraction as a preparative method.

Effect of total body x-radiation on plasma alkaline phosphatase of rats STEPHAN LUDEWIG *Biochemical Lab, Univ. of Virginia, Charlottesville*

The plasma alkaline phosphatase activity of 60-day old male rats was determined after irradiation with doses between 200 r and 600 r. The King-Armstrong method used in the determination of plasma phosphatase was slightly modified. A moderate increase in enzyme activity was noted 24 hours after irradiation. The values decreased after the 2nd day in the 400, 500 and 600 r groups. The length of time that the values remained low was dependent on the dosage. Pair-fed rats served as controls since food intake of exposed animals was influenced by x-radiation. The phosphatase activity was depressed in the plasmas of animals exposed to multiple small doses.

Liberation of amino acids in human seminal fluid FRANK LUNDQUIST (introduced by H. A. LARDY) *Inst. of Legal Medicine, Univ. of Copenhagen, Denmark*

During some attempts to determine the composition of the secretions from the accessory sex glands in man, it was accidentally observed that the amino-nitrogen of semen showed a very rapid increase on incubation. Amino-nitrogen levels of about 200 mg/100 ml were obtained in 2 or 3 hours. Experiments using the manometric ninhydrin method gave evidence that free amino acids were the substances concerned. The proteolytic enzyme responsible for this phenomenon was partly purified through salt fractionation. It has a pH optimum of about 7.5 when casein is used as a substrate. Chromatographic analyses using filter paper showed the same pattern of amino acids in deproteinized filtrates of incubated semen as in filtrates from fibrin incubated with the purified enzyme. A fibrin-like substance has been isolated from fresh semen and was found to give rise to the same amino acids as native semen. Possibly the enzyme concerned is identical with the fibrinol-

ysin observed by Huggins and Neal (*J. Exper. Med.* 76: 527, 1942) in human ejaculate.

Studies on lactalbumin heated with carbohydrate IVAN J. MADER,* LAWRENCE J. SCHROEDER* AND ARTHUR H. SMITH *Dept. of Physiological Chemistry, Wayne Univ. College of Medicine, Detroit, Mich.*

A comparison of *in vitro* and *in vivo* studies was made in an attempt to evaluate the role of heat and carbohydrate concentration in the non enzymatic browning of proteins as exhibited in the Maillard Reaction. Commercial and 'carbohydrate-free' lactalbumin, heated under various conditions, was used in *in vitro* digestion experiments. The conventional formol titration procedure, showed that the rate and amount of digestion of the protein by pancreatin is inversely proportional to the severity of heat treatment. Removal of reducing substances from lactalbumin before heating permits a greater rate and degree of enzyme hydrolysis of the heated product. Microbiological assays for valine, histidine, leucine, phenylalanine, lysine and methionine in acid hydrolysates of the various proteins showed that only lysine was partially destroyed. These observations suggest that the carbohydrate reacts with the protein to form enzyme-resistant materials. A nitrogen balance study in dogs was used to determine the relative effect of heat and of carbohydrate in the alteration of the nutritive value of heated protein. 'Carbohydrate-free' lactalbumin and extracted lactalbumin to which had been added 2 and 5% lactose served as the protein nitrogen sources. The time of autoclaving of these proteins was varied from one-half to one hour. The biological value was high in all cases. However, as either the carbohydrate concentration or the time of heating was increased, the nutritive index of the protein decreased. Lowered digestibility, shown by increased fecal nitrogen, accounted for the decrease in nutritive value.

Quick blood sugar method suitable for routine use and screening EMANUEL E. MANDEL AND RAYMOND H. OWINGS (introduced by OLAF MICKELSEN) *Clinical Pathology Section, Lab. Services, Communicable Disease Center, Public Health Service, Federal Security Agency, Atlanta, Ga.*

In the search for a blood sugar method applicable to large-scale diabetes surveys, modification of a 'bed side' procedure (*J. Lab. & Clin. Med.* 34: 720, 1949) not only lent itself to this purpose but also proved to be a useful routine method. From a mixture of blood and saturated picric acid solution in the proportion of 1:5 or higher, a filtrate is obtained which after addition of 10% sodium hydroxide, boiling and dilution with distilled water is read in a spectrophotometer at wave

length 540 The glucose color reaction is stable for one hour, readily reproducible, and follows Beer's law, it is unaffected by delay in centrifuging or filtering the initial blood-reagent mixture up to 3 days or by minor variations in the boiling time The determination includes non-fermentable reducing substances in the blood, and hence compares well with Folin-Wu's and similar methods while results are consistently higher than those obtained with 'true glucose' methods (SOMOGYI, KINGSLEY) Addition of cadmium sulfate to the picric acid reagent and alkalinizing before filtration approximates results to the true glucose levels In screening for diabetes, expediency is enhanced by 1) using automatic devices such as Cornwall syringes and pipetting machines for volumetric measurements 2) dividing the spectrophotometer scale into groups according to selected blood glucose levels and reporting group designations rather than individual values After the initial centrifugation, 5 technicians can conveniently run 2,000 determinations in less than 4 hours

A continuous indicating recording oxygen cathode

GEORGE H MANGUN AND WALTER D GRIEST *
Dept of Labs, Henry Ford Hospital, Detroit, Mich

A recording oxygen cathode useful in studying tissue oxygen changes has been devised, based on the principle described in 1942 by Davies and Brink It differs principally in the following details 1) Semi-micro electrodes of various metals are employed, 2) Tungsten electrodes 1-20 mm long have proven very useful since they may be inserted readily without causing severe mechanical injury and give reproducible values for many hours, 3) A Ag/AgCl reference electrode is applied directly to the skin via saturated KCl Jelly, 4) A General Motors chopper amplifier of low input resistance is employed Although this amplifier interrupts the current momentarily at 60 cycles/sec, it yields current-oxygen tension curves similar to continuous direct current, 5) The amplifier output is fed into a 0-5 ma Esterline-Angus recording millimeter, 6) Resistors parallel to the cathode circuit provide for rapid calibration Since factors other than oxygen tension affect the rate of arrival of oxygen at the cathode surface, calibrations have been made by gasometric analysis of venous and arterial blood, or the results expressed arbitrarily in terms of microamperes/mm of tungsten wire Tissues rendered completely anoxic yield zero readings, furnishing one known point for calibration Studies have been made on muscle, liver, venous and arterial blood, and subcutaneous tissues, and the effects of nitrogen, oxygen, barbiturates, infra-red heat, and ice water demonstrated Comparative studies with this in-

strument and the oxymograph will be reported elsewhere by Behrmann, Griest, Mangun, Hartman

Determination of fumaric, cis-aconitic and alpha-ketoglutaric acids in rabbit kidney and liver by partition chromatography LAWRENCE M MARSHALL AND FREDERICK D DREW (introduced by VERNON A WILKERSON) *Dept of Biochemistry, Howard Univ College of Medicine, Washington, D C*

The chromatographic analysis of fumaric acid (*J Biol Chem* 179 1127, 1949) has been extended to the determination of alpha ketoglutaric, cis-aconitic and fumaric acid in rabbit kidney and liver Improved rate of flow through silica gel columns was obtained by maintaining constant pressure over the influent Cis-aconitate and alpha ketoglutarate were measured with an influent mixture of tertiary amyl alcohol and chloroform in a ratio (vol/vol) of 1:9 while for fumaric a 1:19 ratio was used Mechanically collected samples, each of 2 ml volume, showed peaks for fumaric, alpha ketoglutaric and aconitic acids at fractions 9, 33 and 56 respectively Effluent fractions were measured spectrophotometrically (λ 230) and by titration Symmetry of the chromatographic curves and a correlation between the 2 methods of measurement for each acid served to characterize the effluent zones Known metabolic acids did not interfere Average percentage recovery of each acid added to tissues exceeded 95 % The average concentrations of fumaric acid in kidney and liver in (mg/100 gm wet tissue) were 3.2 and 2.0 respectively while those of aconitic and alpha ketoglutaric acids were less than 1

Acetylation of p-amino benzoate and related compounds by the rabbit M F MASON, GUS CASTEN* AND ALLAN LINDSAY * *Parland Hospital and Southwestern Med School of Univ of Texas, Dallas*

Following intraperitoneal injection of 200-500 mg of p-amino benzoate in the rabbit, acetylation by the liver attains a maximum rate (= 'Lm acetylaminobenzoate') which is then essentially independent of the plasma concentration of p-amino benzoate achieved The acetylation rate is calculated by measuring the amount of acetylaminobenzoate appearing in the urine and accumulating in the body per unit time Calculations based on the ultimate plasma concentrations obtained after similar injections into nephrectomized rabbits indicate that the free and acetylated forms are distributed in a fluid mass approximately 30% of the body weight of the rabbit Preliminary estimates of Lm acetylsulfanilamide, and Lm acetyl p-amino hippurate, have also been made

Deamination and denaturation of crystalline egg albumin PAUL H MAURER* AND MICHAEL HEIDELBERGER *Depts of Biochemistry and Medicine, Columbia Univ College of Physicians and Surgeons, New York City*

Deamination of crystalline egg albumin (Ea) beyond 30-35% at pH 4 and 0° C leads to a deaminated denatured Ea (Fraction A), the word 'denatured' being used to indicate insolubility at the isoelectric point (*Federation Proc* 8 227, 1949) The physical, chemical and immunological properties are different from those of acid denatured Ea (DnEa) Treatment of Fraction A at 22-24° C and pH 1.5, conditions leading to acid DnEa from Ea, gives an A Dn preparation with physical, chemical and immunological properties differing little from those of the original A fraction A partly deaminated (25-30%), undenatured Ea (Fraction B) gave at pH 1.5 a B Dn preparation with properties similar to those of acid DnEa The structure arrived at by partial unfolding of the protein molecule during deamination is therefore different from that of acid DnEa It is more resistant than Ea or Fraction B to acid denaturation and is more stable than DnEa to aggregating influences, and hence has a smaller particle weight than DnEa preparations with the possible exception of heat DnEa

Hydrolysis of protamines by cathepsins MARY E MAVER AND ANTOINETTE E GRECO* *Natl Cancer Inst, Natl Insts of Health, USPHS, Bethesda, Md*

The role of cathepsins in nuclear metabolism has been studied by following the activity of these intracellular proteinases on the constituents of the nucleus The ability of calf spleen and thymus cathepsin preparations to hydrolyze thymus nucleoproteins and to depolymerize the liberated nucleic acid has been reported previously The cathepsin preparations also hydrolyzed the protamines, salmine and clupein, which are combined with desoxyribonucleic acid in the ripe sperm heads of salmon and herring The degree of hydrolysis was found by determining the increase in soluble N, amino N, arginine, serine and proline when the digests were precipitated with methyl alcohol The hydrolyses were markedly activated by cysteine and had an optimum at pH 5.0 Cathepsin preparations from calf and beef spleen, calf thymus and 2 transplantable rat tumors, a lymphosarcoma, and a hepatoma showed protaminase activities which corresponded in most cases to their proteolytic activities on hemoglobin

Relation of sulfhydryl and disulfide groups in ferritin to its vasodepressor activity ABRAHAM MAZUR AND EPHRAIM SHORR* *Dept of Medicine, Cornell Univ Medical College and The New York Hospital, New York City*

The vasodepressor activity of solutions of crystalline ferritin, as measured by its effect in the rat mesoappendix test, is shown to be related specifically to sulfhydryl groups Treatment of ferritin with reagents such as o-iodosobenzoate, p-chloromercuribenzoate, iodoacetate, iodoacetamide, or oxygen in the presence of a trace of Cu^{++} , leads to the disappearance of the SH groups as well as of the vasodepressor activity Reactivation can be obtained with cysteine, ascorbic acid or reduced glutathione When the vasodepressor activity of ferritin is inactivated by incubation with normal liver slices in oxygen, reactivation occurs after treatment with the above reducing agents, indicating a similar chemical mechanism Normal liver slices in oxygen oxidize the SH groups of ferritin, no oxidation takes place in nitrogen Saline extracts of aerobic liver slices, centrifuged free of cells, will aerobically inactivate the vasodepressor activity of ferritin as well as oxidize its SH groups Reactivation is obtained with cysteine or ascorbic acid Evidence is presented to show that the ferritin normally present in liver is predominantly in the -S-S- or inactive form but that after being subjected to anaerobic conditions the ferritin is converted to the SH or vasotropically active form Normal liver slices exposed to nitrogen and then returned to oxygen suffer an impairment in their ability to inactivate the vasodepressor activity of ferritin parallel with an impairment in their ability to oxidize the SH groups of ferritin

Enzymatic anodic phosphorylation in rat brain homogenates W K McEWEN* AND JOHN J EILER *College of Pharmacy, Univ of California Med Center, San Francisco, Calif*

A smooth platinum anode was used to accept electrons from the anaerobic oxidation of succinate in fortified rat brain homogenates A 3.3×10^{-3} M ferro/ferricyanide couple was employed as a mediator The homogenates were similar to those used in our previous work (EILER AND McEWEN *Arch Biochem* 20 163, 1949) including the use of pentobarbital to suppress the oxidation of substrates other than succinate During the course of a run the amperage was relatively constant and the coulombs produced were equivalent to the oxygen consumed by an identical homogenate under aerobic conditions The phosphate esterification was about 3 of that of the oxygen control It can be shown that both the current flow and the phosphate esterification are dependent upon active enzymes The addition of malonate depressed markedly the flow of current and abolished the phosphorylation In the absence of added succinate, or when heated brain tissue was substituted for normal brain tissue, there was neither significant current flow nor phosphoryla-

tion From the evidence available it is probable, under the conditions of anodic phosphorylation, that cytochrome oxidase is not involved in either electron transport or phosphate esterification. The general applicability of this method and its significance in the study of oxidative phosphorylation will be discussed.

Investigation of relation of insulin to lipid metabolism, with special reference to phospholipid
EVA C MCGHEE,* EVANGELINE PAPAGEORGE,*
WALTER L BLOOM* AND GEORGE T LEWIS
Biochemistry Dept, Emory Univ School of Medicine, Emory Univ, Ga

In a series of 5 experiments rabbits were used to study the effect of insulin on blood lipid components and on brain and liver lipid phosphorus. Massive doses of insulin were administered to 3 groups of animals. One was given insulin alone, the second and third were given subsequent injections of lecithin and glucose, respectively. Insulin deficiency was studied in alloxan diabetic animals, and lecithin tolerance, in normal rabbits. Normal values for tissue lipid phosphorus were obtained from a control group. A summary of the statistical appraisal of the data obtained is as follows. Heavy doses of insulin produce a significant decrease in the blood levels of total fatty acids and glucose, and a decrease in lipid phosphorus which approaches significance. These decreases appear to be a secondary insulin effect inasmuch as they do not occur when glucose is administered in quantities sufficient to maintain the blood glucose above a convulsive level. A significant increase in blood sugar follows the administration of lecithin to normal rabbits. However, the injection of lecithin does not alter the course of insulin action on blood sugar in the insulinized animal. No significant change in liver lipid phosphorus was noted under our experimental conditions. Hyperinsulinism produces a significant decrease in brain lipid phosphorus. This decrease is independent of the blood glucose level and is not alleviated by lecithin in the amount given.

Histamine release from rabbit blood cells by pure compounds—competitive inhibition phenomena
FLOYD C MCINTIRE* AND L W ROTH
Depts of Biochemistry and Pharmacology, Abbott Labs, North Chicago, Ill

In our investigations on the mechanism of histamine release from rabbit blood cells we have found that the histamine is released very rapidly by 2 series of pure compounds (primary aliphatic amines and alkyl β -carbomethoxypyridinium salts) and that closely related compounds will competitively inhibit this histamine release. At 37°C n-octadecylamine 8×10^{-5} M, will release all or nearly all of the histamine from the normal

rabbit blood cells. At the same concentration n-hexadecylamine is less effective and n-dodecylamine releases histamine only slightly. The histamine release by the primary amine, octadecylamine, is 50–80% inhibited by the simultaneous addition to the blood of the tertiary amine, N-dimethyloctadecylamine or N-dimethyldodecylamine, in a ratio of 3 molecules/molecule of octadecylamine. A maximum histamine release results also when n-hexadecyl- β -carbomethoxypyridinium bromide is used at a concentration of 8×10^{-5} M. The histamine release by this compound is almost completely blocked by the simultaneous addition of 1) aliphatic quaternaries, e.g. N-trimethyloctadecylammonium chloride, or 2) alkyl pyridinium quaternaries where the β -carbomethoxy is replaced by a carbamyl group or halogen, e.g. n-hexadecyl- β -carbamylpyridinium bromide or n-hexadecyl- β -bromopyridinium bromide.

At 37°C the histamine release by these compounds is 90% complete in one minute. The fact that pure compounds will release histamine and the rapidity of the reaction cast doubt upon the theory that the release of histamine requires a protease activation as a preliminary step. 1,10-Diaminodecane and 1,6-diguanidylhexane (MacINTOSH AND PATON *J Physiol* 109:190, 1949), 5×10^{-4} M, released little or no histamine from rabbit blood cells.

Chemical components and metabolic activities of relapsing fever spirochete (*Borrelia novyi*).

RALPH W MCKEE AND QUENTIN M GEIMAN*
Dept of Biological Chemistry, Harvard Med School, and Dept of Tropical Public Health, Harvard School of Public Health, Boston, Mass

Studies of *B. novyi* have been conducted to determine the biological nature of the spirochetes and to indicate a logical approach to the formulation of a nutrient culture medium which will produce *in vitro* growth and multiplication. The organisms were isolated from the blood of infected white rats by differential flotation and centrifugation. A partition of the phosphorus (P) components of the isolated spirochetes was conducted according to the method of Schmidt and Thannhauser (*J Biol Chem* 161:83, 1945). The trichloroacetic acid insoluble material was extracted with fat solvents and the extract analyzed for total lipid P (2.01 mg/10⁸ organisms), lipid (382 mg) and cholesterol (73 mg). The remainder of the trichloroacetic acid insoluble fraction was partitioned and analyzed for desoxyribonucleic acid P (0.694 mg), ribonucleic acid P (1.565 mg) and phosphoprotein P (0.606 mg). The trichloroacetic acid soluble fraction was analyzed for inorganic P (0.352 mg), 15-minute hydrolyzable P (0.691 mg) and residual organic P (0.352 mg). The total nitrogen of the isolated spirochetes was 99 mg.

The organisms are being analyzed for amino N and amino acids. Glycolytic studies show that *B. novyi* utilize large quantities of glucose (0.4 mM) but only 0.1 mM of oxygen/hr. About 65% of the glucose was accounted for as accumulated lactic acid. Thus no more than 10% of the consumed glucose could have been oxidized completely to carbon dioxide and water. Use of the accumulated data has been made in preliminary cultivation studies. Growth and prolonged motility of the spirochetes *in vitro* have been obtained but without multiplication.

Plasma growth and inhibitory factors for malarial parasite (*Plasmodium knowlesi*) RALPH W. MCKEE AND QUENTIN M. GEIMAN* *Dept. of Biological Chemistry, Harvard Med. School, and Dept. of Tropical Public Health, Harvard School of Public Health, Boston, Mass.*

Although *in vitro* multiplication of *P. knowlesi* can be obtained consistently in cultures using a synthetic medium, the addition of normal monkey plasma enhances growth and multiplication. The effective components of plasma are only slowly dialyzable but they can be separated by prolonged dialysis through cellophane membranes. In a study to determine the animal species yielding the highest plasma concentration of the stimulatory agents, blood from cattle, man and monkey were studied. Bovine plasma inhibited growth while human plasma stimulated growth to only a small extent. Monkey plasma produced the best results with marked enhancement of growth (multiplication approximately doubled when 20% of the culture was plasma). Simultaneous perfusion cultures (*J. Exper. Med.* 84: 583, 1946) were carried out in an effort to separate by dialysis any growth stimulatory material. Very striking results were obtained indicating that bovine plasma contains stimulatory materials but their effects were masked by the inhibitory substances which dialyzed away faster than did the active components. Tests of the dialysate showed definite inhibition of growth while the impermeate produced stimulatory effects with *P. knowlesi*. The implications of these findings are two-fold. Not only is the stimulatory effect of importance for a complete evaluation of the nutrient requirements and for prolonged cultivation but the chemical differences among various animal species, particularly the presence of inhibitory substances, may help to explain host-parasite specificity.

Effect of acute choline deficiency on tissue lipids of young puppies J. M. MCKIBBIN *Dept. of Biochemistry, Syracuse Univ. College of Medicine, Syracuse, N. Y.*

Total lipid nitrogen, phosphorus, choline and sphingosine were determined on purified extracts of 10 tissues of choline deficient puppies and their

littermate controls. Total liver lipid phosphorus and nitrogen were not decreased in the deficient animals although considerable variation was observed in both groups. Lipid choline/gm of dry lipid free tissue was not significantly decreased but the percentage of lipid nitrogen represented by choline was very significantly decreased. Sphingolipids were significantly increased in the deficient dog livers on both the per gram and percentage of lipid nitrogen basis. These are interpreted as sphingomyelins. Lecithins were therefore significantly decreased on both a per gram and percentage basis in the deficient livers. The pattern of lipid nitrogen is altered more than the absolute amounts of the various lipids. Blood plasma total lipid phosphorus and nitrogen were reduced to an average of about one-third that of the controls. The choline to phosphorus ratio was not reduced but the sphingosine to phosphorus ratio was increased in the deficient plasmas. It is concluded that sphingomyelins are replacing lecithins in the plasma. The intestine phospholipids were decreased about 15% in the deficient animals and this decrease was not confined to the choline phospholipids. Skeletal muscle phospholipids were slightly lowered due principally to an 18% reduction in the choline phospholipids. The lipids of lung, cerebrum, spleen, pancreas, kidney and heart were rigidly maintained in this severe deficiency.

Factors affecting synthesis of acetylcholine (ACh) by rat brain cortex slices HUGH McLENNAN* AND K. A. C. ELLIOTT *Montreal Neurological Inst., McGill Univ., Montreal, Canada*

In confirmation of work of Mann, Tennenbaum and Quastel, the synthesis of free ACh by brain cortex slices in the presence of glucose and oxygen was found to be greatly stimulated by the presence of 0.027 M K^+ , this effect occurred in bicarbonate but not in phosphate buffered medium and was inhibited by high Ca^{++} concentration. Contrary to the report of the previous authors, no equilibrium concentration of free ACh was found but synthesis continued for several hours, the rate tended to increase during the first 2 hours and addition of ACh often accelerated, never inhibited, the synthesis. No consistent change in the bound ACh was produced by added K^+ . The synthesis was very sensitive to the concentration of Ca^{++} . Synthesis was low without Ca^{++} maximal at 1.3 mM Ca^{++} , and fell off sharply with higher concentrations. Similar but less marked dependence on Mg^{++} was observed. Citrate inhibited synthesis in Ca^{++} -containing medium. Synthesis was greatly reduced in unbuffered medium containing 1.3 mM Ca^{++} or in debicarbonated serum. The presence of bicarbonate- CO_2 was evidently essential and experiments indicated an optimal

bicarbonate concentration (at nearly constant pH) around 25 mM. Bicarbonate could not be replaced by oxaloacetate, when glucose and bicarbonate were present, oxaloacetate and pyruvate caused some inhibition. Under otherwise optimal conditions sodium pentobarbital (Nembutal) inhibited synthesis by about 50% at a concentration, 0.5 mM, which inhibited respiration by only about 15%. Metrazol, 5 mM increased synthesis, higher concentrations were inhibitory, with little effect on respiration.

Mechanism of carbon dioxide fixation in *M. lysodeikticus* ROSABELLE McMANUS (introduced by M. F. UTTER) *Dept. of Biochemistry, Western Reserve Univ. School of Medicine, Cleveland, Ohio*

The oxalacetic carboxylase reaction was first demonstrated in *M. lysodeikticus* and its apparent reversibility shown by incorporation of $C^{14}O_2$ in the β -COOH of oxalacetate during its breakdown to pyruvic acid and CO_2 in the presence of $C^{14}O_2$. We have continued the study of this reaction in *M. lysodeikticus* using an aqueous extract from disintegrated cells as enzyme source and have demonstrated certain properties of this system which differ from the system occurring in pigeon liver. In contrast to the stimulatory effect of ATP on the fixation reaction catalyzed by pigeon liver, ATP fails to enhance the fixation of CO_2 by *M. lysodeikticus*. That muscle ATP is active under the conditions of this study was established by demonstrating its participation in the hexokinase reaction and in the phosphopyruvate transphosphorylase reaction using the same bacterial preparation. After purification of oxalacetate from the incubation mixture by means of chromatographic techniques, there was no indication that substances other than oxalacetate contained radioactivity. Under our experimental conditions, fixation of CO_2 in oxalacetate formed enzymatically from malate appears to be comparable to fixation in synthetic oxalacetate. Possible operation of Ochoa's 'malic' enzyme system in the bacteria prompted study of fixation in the presence of malate. In contrast to results with pigeon liver where there is some fixation of CO_2 in malate, the bacterial system fails to fix CO_2 into malate even in the presence of TPN although good fixation is occurring in oxalacetate, precluding malate as an intermediate in this system.

Composition and densities of β -lactoglobulin crystals in sucrose and in serum albumin solutions T. L. McMEEKIN, M. L. GROVES* AND N. J. HIPP* *Eastern Regional Research Laboratory, Philadelphia, Pa.*

The fact that the density of a virus as determined by ultracentrifugal studies varies in different suspending media (SMADL, PICKELS AND SHEDLOVSKY *J. Exper. Med.* 68: 607, 1938) sug-

gested that a study of the densities and composition of protein crystals suspended in similar solutions would be of value in interpreting the behavior of the virus. The composition and densities of β -lactoglobulin crystals have been determined in sucrose and in serum albumin solutions. Several relations were found between the composition of the crystal and the suspending medium which are consistent with the variations in the density of the virus in similar solutions as determined by ultracentrifugal studies. It was found that sucrose penetrates the protein crystal, and that the concentration of sucrose in the water of the crystal varies with the concentration of sucrose in the suspending medium. In contrast, serum albumin does not penetrate the β -lactoglobulin crystal. It was also found that protein crystals suspended in sucrose solutions lose water and that the loss in water is directly proportional to the difference between the osmotic pressure of the sucrose in the water of the protein crystal and the osmotic pressure of the suspending sucrose solution. These findings indicate that the value for density of a virus as determined by ultracentrifugal studies in serum albumin solutions is less likely to be in error than the value obtained in sucrose solutions. Also, the calculated nonsolvent water or 'bound' water of a protein crystal is shown to vary with the environment.

Lipids of peripheral nerve after nerve crush (axonotmesis) A. R. McNABB* AND R. J. ROSSITER *Dept. of Biochemistry, Univ. of Western Ontario, London, Canada*

Previously it has been shown (*Biochem. J.* 45: 500, 1949) that when a cat sciatic nerve undergoes Wallerian degeneration after nerve section (neurotmesis) there is at first an increase in the content of water and a temporary decrease in the content of neutral fat. After 8 days there is a steady decrease in the concentration of both total lipid and myelin lipid, i.e. cerebroside, free cholesterol and sphingomyelin, the three substances which we have suggested are the principal lipid components of the myelin sheath of a mammalian nerve. There is also a remarkable esterification of cholesterol, greatest at 16 days. For the first 32 days after nerve crush (axonotmesis) the changes in the concentration of water and lipid were essentially the same as those following nerve section. Then from 32 to 64 days the concentration of the various lipids decreased less rapidly in the crushed nerve, and by 64 days the concentration of lipids in the crushed nerve had commenced to increase. The concentration of ester cholesterol reached a maximum between 16 and 32 days, and thereafter decreased progressively, none remaining at 144 days. The slower decrease in the concentration of the lipids between 32 and

64 days and the actual increase in the concentration of these lipids after 64 days undoubtedly represent the formation of new myelin sheaths, and other lipid-containing structures, following upon the regenerative peripheral outgrowth of new axons. The individual myelin lipids, i.e. cerebroside, free cholesterol and sphingomyelin, returned at similar rates.

Histochemical distribution of indophenol oxidase and acid phosphatase in rat cortex J A MEATH AND A POPE (introduced by J FOLCH) *McLean Hospital, Waverley, Mass., and Harvard Med School, Boston, Mass.*

The cytological distribution of indophenol oxidase (cytochrome oxidase) and of acid phosphatase was determined histochemically in the motor somatosensory and entorhinal areas of rat cortex. Coronal sections of unfixed tissue were cut at -10°C and used alternately for histochemical and histological study. Indophenol oxidase activity, determined by a modification of Graf's method, was greater in isocortex (motor and somatosensory) than in allocortex (entorhinal), the increase being the outer lamina (layers I-IV). In motor cortex the greatest activity was in layers I, II and IIIA, in somatosensory cortex in layers I, III and IV. Intensity of oxidase reaction was similar to degree of vascularization, both possibly reflecting the local metabolic rate. Acid phosphatase activity, determined by a modification of Gomori's method, was greatest in axones and in the larger pyramidal cells irrespective of location, their cell body and apical dendrites being most intensely stained. Smaller neurones were less intensely stained. Glial elements were unstained with the exception of subpial astrocytes. With unfixed frozen cortex, the phosphatase reaction differed quantitatively and qualitatively from that observed when acetone fixed and paraffin-embedded tissue was used. Optimal incubation time was 3 hours for the former as compared to 72-96 hours for the latter. In the former, the cytoplasm of the neurones was maximally stained. In the latter, staining was usually more intense in the nucleolus and nucleus than in the cytoplasm.

Effect of keto acids on the in vitro metabolism of glutamine and glutamic acid ALTON MEISTER (introduced by JESSE P GREENSTEIN) *National Cancer Inst., Bethesda, Md.*

The effect of a number of acids possessing α , β , γ , or δ -keto groups on the desamidation of glutamine by liver homogenates and partially purified liver fractions has been investigated. Only α -keto acids produced significant acceleration of glutamine desamidation. Although α , γ -diketo acids accelerated this reaction this was due to pyruvate formed by hydrolysis of the diketo acids. Protein fractions were obtained from rat

liver homogenates which exhibited a 30-fold increase in desamidase activity and which also exhibited considerable transaminase activity. With these preparations no desamidation of glutamine occurred in the absence of pyruvate, while in the presence of pyruvate the products were alanine, α -ketoglutarate and ammonia. Similar results were obtained with α -ketoisocaproate and phenylpyruvate, although desamidation of glutamine in the presence of these keto acids occurred more rapidly than did transamination. The amino acids were identified and quantitated by microbiological and chromatographic methods, α -ketoglutarate was identified as the 2,4 dinitrophenylhydrazone. In experiments with glutamine labelled with N^{15} in the amide group and with added pyruvate, all of the isotope was recovered as inorganic ammonia. Pyruvamide did not substitute for pyruvate nor was this compound desamidated in this system, while the γ -methylamide of glutamic acid was considerably less active than glutamine or glutamic acid.

Studies in the metabolism of L-threonine HERBERT L MELTZER* AND DAVID B SPRINSON *Dept. of Biochemistry, Columbia Univ., New York City*

L-threonine, containing C^{14} in the γ -carbon atom and N^{15} in the amino group, has been prepared and fed to rats. Urinary acetyl-L- α amino- γ -phenylbutyric acid and hippuric acid revealed that at least 25% of the administered threonine was converted to acetate while conversion to glycine occurred to a smaller extent. Almost all of the activity of the excreted acetate was found in the methyl carbon. The ratio of activities in the internal organ cholesterol and fatty acids suggests that the acetylating agent formed from threonine is acetate. The N^{15} concentration of the internal organ serine was higher than that of the glutamic acid, indicating a direct conversion of threonine to glycine followed by formation of serine. Isotopic threonine was isolated from the internal organ proteins by large-scale starch chromatography (MOORE AND STEIN *J Biol Chem* 178: 53, 1949). By the analysis of the internal organ threonine isolated after feeding N^{15} -L-leucine it was demonstrated that the carbon chain of threonine, like that of lysine, does not accept nitrogen from the metabolic pool (Cf. ELLIOTT AND NEUBERGER *Biochem J* 45, no 2 viii, 1949). When the labeled threonine was added to duck blood *in vitro* the isolated hemin had C^{14} and N^{15} in agreement with the known utilization of acetate and glycine for heme synthesis (RADIN, RITTENBERG AND SHEMIN *Federation Proc* 8: 240, 1949).

Chemical and biological properties of biotin sulfide DONALD B MELVILLE, DOROTHY S GENGHOF* AND JOHANNA M LEE* *Dept. of Bio-*

chemistry, Cornell Univ Med College, New York City

A crystalline compound highly active as a yeast growth factor was isolated from esterified biotin concentrates from milk, and was shown by analysis and by synthesis from biotin to be the methyl ester of biotin sulfoxide. The free acid was prepared by treatment of biotin with the theoretical amount of hydrogen peroxide in acetic acid solution. Under these conditions two diastereoisomeric forms of biotin sulfoxide are produced, by virtue of the asymmetric nature of the sulfoxide grouping. The isomer produced in largest amount is dextrorotatory and possesses essentially the same growth-promoting activity for *Saccharomyces cerevisiae* as biotin, conversion of this isomer to the methyl ester yields a compound identical with that isolated from esterified biotin concentrates. The other isomer is levorotatory and is not more than one-thousandth as active as biotin toward *Saccharomyces cerevisiae*. Both isomers on further oxidation with hydrogen peroxide yield biotin sulfone. The dextrorotatory sulfoxide shows the same growth activity as biotin toward *Lactobacillus arabinosus*, but negligible activity, compared to biotin, for *Lactobacillus casei*. The levorotatory sulfoxide shows approximately 5% of the activity of biotin toward both these microorganisms. The injection of either the dextro or levo sulfoxide into biotin-deficient rats, at a level of 10 γ daily, did not alleviate the deficiency symptoms.

Nitrate and ammonia assimilation in plants JULIUS L MENDEL AND DONALD W VISSER (introduced by R J WINZLER) *Dept of Biochemistry and Nutrition, Univ of Southern California School of Medicine, Los Angeles*

A comparison of the assimilation of nitrate and ammonia in nitrogen deficient tomato plants was investigated by measuring the incorporation of N^{15} after administration of N^{15} labelled nitrate or N^{15} labelled ammonia. The plants were divided into root, leaf, and stem tissues which were fractionated into various nitrogenous constituents (ammonia, amides, and amino acids). For a given tissue, the N^{15} distribution followed the same general pattern whether nitrate or ammonia were the nitrogen source, the highest atom percentage excess of N^{15} in both cases was found in the ammonia and amide fractions. In the plants given ammonia, there was a higher atom percentage excess of N^{15} for each nitrogenous constituent in the roots than in the leaves, while in the plants given nitrate, there was a higher atom percentage excess of N^{15} in the leaves than in the roots.

Nature of the intrinsic factor CURTIS E MEYER, SAMUEL H EPPSTEIN*, FRANK H BETHELL* AND BYRON E HALL * *Research Labs, Upjohn Company, Kalamazoo, Mich, Thomas Henry Simp-*

son Memorial Inst, Ann Arbor, Mich, and Mayo Clinic, Rochester, Minn

During the course of concentrating the intrinsic factor from hog intestines, certain similarities between this factor and lysozyme became apparent. It has been observed that lysozyme derived from egg white has the property of combining with vitamin B-12, thus rendering it unavailable to *Lactobacillus lactis* Dorner and *Escherichia coli*. Oral administration of 9 μ g of vitamin B-12 in the form of the complex, daily, to patients with pernicious anemia results in remission, with characteristic reticulocyte response and erythropoiesis.

Hydrolysis of sulfated mucopolysaccharides by testicular hyaluronidase KARL MEYER AND MAURICE M RAPPORT* *Dept of Medicine, Columbia Univ, College of Physicians and Surgeons, New York City*

Chondroitin sulfate of hyaline cartilage has been shown to be hydrolyzed by testicular, but not by pneumococcal (MEYER, K, E CHAFFEE, G L HOBBY AND M H DAWSON *J Exper Med* 73 309, 1941) or streptococcal (HUMPHREY, J H *Biochem J* 40 442, 1946) extracts active as hyaluronidases. The hydrolysis of chondroitin sulfate was believed to be due to an enzyme distinct from hyaluronidase (MEYER, K *Physiol Rev* 27 335, 1947). Comparison of the activity of 10 testicular hyaluronidases of greatly varying potency and mode of preparation toward hyaluronate and 3 different samples of chondroitin sulfate showed a constant ratio of the activities on the 2 substrates. The depolymerization was measured by turbidimetric and reductimetric assay methods for both activities. These experiments indicate that testicular hyaluronidase hydrolyzes chondroitin sulfate. Other as yet unidentified sulfated mucopolysaccharides isolated from heart valves, tendon and other connective tissues are hydrolyzed by testicular hyaluronidase at rates similar to that obtained with hyaluronate as substrate.

Pasteur effect in dead yeast O MEYERHOF AND SILVIO FIALA * *Dept of Physiological Chemistry, Univ of Pennsylvania School of Medicine, Philadelphia*

The quickly dried yeast which was recently described (O MEYERHOF *J Biol Chem* 180 575, 1949) has been used for the study of the Pasteur effect. This yeast preparation which has preserved its ATP-ase and which ferments sugar with constant speed shows a respiration similar to living yeast. Quickly dried brewers' yeast has a very low uptake of oxygen but quickly dried bakers' yeast shows an appreciable respiration in the presence of sugar. The Pasteur quotient, moles carbon dioxide disappeared/moles oxygen consumed, is around two like that in the living

yeast With such a yeast, in which phosphate does not accumulate anaerobically, accumulation of phosphate occurs in the presence of oxygen coupled with respiration Substances which inhibit the oxidative phosphorylation at least partially without inhibiting the respiration as nitrophenol and dinitrophenol inhibit also the Pasteur effect The same substances do not inhibit anaerobic phosphorylation The meaning of these observations for the theory of the Pasteur effect will be discussed

Micro-method for determining carbohydrate components of gastric mucin MORITZ MICHAELIS*, FRANKLIN HOLLANDER AND CARYL TARR* *Gastro-Enterology Research Lab, Mount Sinai Hospital, New York City*

Methods in current use for determining gastric mucin are based on estimations of either tyrosine for the protein moiety, or total reducing matter or glucuronic acid for the prosthetic group These methods all assume that the component being determined is an indicator of the total amount of mucin, even for mixed stomach contents which contains two or more varieties of mucoprotein This assumption still remains to be validated The present report describes a relatively simple procedure for the simultaneous determination of glucuronic acid, glucosamine and reducing substance Total reducing power is measured by the arseno-molybdate methods (Nelson), and glucosamine by Ehrlich's reaction with p-dimethylaminobenzaldehyde according to Elson and Morgan, as modified by Blix A third aliquot is treated with $\text{Ba}(\text{OH})_2$ and ZnSO_4 under critical conditions to precipitate glucuronic acid quantitatively, as checked with Dische's carbazole reaction, without removing any of the other components Total reducing power is measured in the supernatant fluid, the difference between this and the initial reducing power gives glucuronic acid This procedure, when tested on mixtures of the pure carbohydrates in question, in quantities of the order of 35-55 γ/ml , has been found reliable to about 5% The entire determination involves a single precipitation and two series of colorimetric readings This procedure is now being adapted to the study of gastric mucin following acid hydrolysis, with a view to its ultimate use in accurately determining mucin content of various gastrointestinal secretions

Studies on the orcinol method for determining pentoses GAIL LORENZ MILLER, ELIZABETH ESHELMAN MILLER*, AND RICHARD H GOLDER* *Inst for Cancer Research and the Lankenau Hospital Research Inst, Philadelphia, Pa*

Bial's color test for pentoses has evolved from a qualitative to a quantitative status, yet the effects of the principal variables have been but partially

investigated Studies were, therefore, made of the effects of the concentrations of orcinol, iron and HCl , and of the time of heating, on the development of color Ribose nucleic acid was used as the test substance Optimum results were obtained with a reagent containing 0.4 gm of ferric alum and 2 gm of orcinol in 100 ml of concentrated HCl , added in equal volume to the aqueous sample to be tested, and heated for 45 minutes in a constant boiling water bath The rate of color development and the absorption spectrum of the final color, obtained with ribose nucleic acid, were then compared with corresponding rates and spectra obtained with adenosine-3-phosphate, adenosine-5-phosphate and free ribose The different test substances developed colors at decreasing rates in the order adenosine-5-phosphate, ribose, adenosine-3-phosphate, and ribose nucleic acid The total color intensities were, however, the same per unit ribose content, except for that produced by the ribose nucleic acid which was only 63% of the others The absorption spectra were essentially identical The findings extended and, in part, confirmed those of previous investigators

Plasma protein synthesis observed in direct study of the liver with aid of lysine- $\epsilon\text{-C}^{14}$ L L MILLER, C G BLY*, M L WATSON* AND W F BALE *Depts of Radiation Biology and Pathology, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*

A direct study of the isolated surviving rat liver *in vitro* yields evidence that the liver synthesizes all plasma albumin and fibrinogen and at least 80% of the plasma globulin fraction Livers are obtained from adult Wistar strain rats and rapidly incorporated in a simple system for the continuous perfusion of isolated intact organs with heparinized oxygenated blood at known temperature and pressure With the aid of lysine $\epsilon\text{-C}^{14}$ the liver is found to respond to variations in amino acid substrate in a fashion qualitatively and quantitatively analogous to that of the intact animal Very little plasma protein is synthesized when the liver is offered only lysine $\epsilon\text{-C}^{14}$ in the perfusing blood The addition of the essential amino acids enhances plasma protein synthesis tenfold Protein synthesis is further increased by the simultaneous addition of the non essential amino acids The addition of extra glucose to the blood slows the disappearance of the free amino acids, but enhances not only the plasma protein production but also the apparent deposition of new liver tissue protein When under optimal conditions for plasma protein synthesis DL lysine- $\epsilon\text{-C}^{14}$ is replaced by D lysine- $\epsilon\text{-C}^{14}$, protein synthesis is less than 10% of that seen with the DL lysine- $\epsilon\text{-C}^{14}$ A comparison of the rat liver with

the surviving posterior half of the rat carcass including gonads and kidneys (BLX, C G, L L MILLER, AND W F BALE *Federation Proc*, this issue) demonstrates the dominant role of the liver in plasma protein synthesis

Factors affecting pyruvate and lactate metabolism in cardiac muscle slices O NEAL MILLER AND ROBERT E OLSON (introduced by HALVOR N CHRISTENSEN) *Dept of Nutrition, Harvard School of Public Health, and Dept of Biological Chemistry, Harvard Med School, Boston, Mass*

Previous experiments with radioactive carboxyl-labeled pyruvate in this laboratory (*Federation Proc* 8 391, 1949) have shown that only part of the pyruvate which disappears in cardiac muscle slices undergoes oxidation to carbon dioxide. In the present investigation the effect of varying initial concentrations of pyruvate and lactate upon oxygen consumption and disappearance of these substrates, the effect of varying concentrations of carboxyl- and carbonyl-labeled pyruvate upon $C^{14}O_2$ production, and the effect of certain inhibitors of glycolysis upon pyruvate and lactate utilization have been studied. Slices of cardiac muscle from healthy ducklings fed *ad libitum* were incubated with pyruvate or lactate at concentrations of 2-40 mM/l in Warburg vessels at 37° for one hour. Changes in the amounts of pyruvate and lactate in these vessels were determined chemically and the rate of oxidation of radioactive substrates, when present, was determined by counting the $C^{14}O_2$ trapped in the center well. It was found that both the disappearance and oxidation of lactate and pyruvate increased with increases in initial concentration of substrate. At 2 mM/l of pyruvate the $C^{14}O_2$ from labeled pyruvate amounted to 30% of the total, or an amount equivalent to the stimulation of respiration caused by addition of substrate, while at 40 mM/l it amounted to 90% of the total. At all concentrations of pyruvate and lactate, the amount of disappearance was greater than could be accounted for by interconversion or oxidation. At 10^{-4} M iodoacetate and 10^{-3} M arsenate, pyruvate and lactate utilization were reduced without change in the respiration. Fluoride at 10^{-4} M reduced pyruvate but not lactate utilization.

A study of the scattering of light in myosin solutions W F H M MOMMAERTS (introduced by GEORGE W SCHWERT) *Dept of Biochemistry, Duke Univ School of Medicine, Durham, N C*

Myosin was obtained in crystalline form, and the homogeneity of the preparations was controlled by ultracentrifugation. The scattering properties of myosin solutions were studied after ultracentrifugal clarification by measuring the absolute scattering intensity and the dissymmetry of the forward and backward scattered light

at various concentrations and at two different wavelengths. The dissymmetry studies, interpreted with the aid of Debye's theory, indicate a particle length of about 2000 Å. The molecular weight is computed from the absolute turbidity is between 1 and 1.6 million. These results are in good agreement with ultracentrifugal and other data. Actomyosin solutions show a much higher turbidity. The dissymmetry is, even at high dilution, considerably higher than the limited value for very long rods, so that no quantitative deductions are permissible. Upon addition of ATP to the actomyosin, the turbidity decreases considerably, indicating dissociation of the actomyosin. At high concentration of the protein, the dissymmetry increases under influence of ATP, but this is not the case for dilute solutions. No contraction of dissolved particles is indicated.

Determination of total serum bilirubin FERRIN B MORELAND, WILLIAM W O'DONNELL AND JOSEPH H GAST, with the technical assistance of MARIE MCGINN (introduced by J M JOHLIN) *Dept of Biochemistry, Baylor Univ College of Medicine, and Veterans Admin Hospital, Houston, Texas*

The use of sulfanilamide instead of sulfanilic acid in the Malloy-Evelyn diazotization of bilirubin gives a much more rapid color development (maximum within 5 min instead of 30-40 min), the intensity is about the same. Sulfanilamide can also be used as an artificial standard for the bilirubin determination, developing a color by the usual coupling with N-(1-naphthyl)-ethylene-diamine dihydrochloride after diazotization. With the Klett-Summerson photoelectric colorimeter, using the green filter #54 (maximum transmission at 525-530 mμ), it has been found that 1 mg sulfanilamide is equivalent in color produced to 2.95 mg bilirubin. Several samples of sulfanilamide, including one which we recrystallized, all gave the same factor, thus avoiding the variability of commercial bilirubin and giving the clinical laboratory a simpler, more stable, more reliable standard. In the determination of bilirubin, more color developed when methyl alcohol was used than with ethyl alcohol. For this reason and because of the easier availability of methanol to physicians' and commercial laboratories, the use of methyl alcohol is recommended. The alcohol should be redistilled, otherwise some samples yield less color than others. To avoid errors inherent in low optical densities, undiluted serum should be used when the bilirubin concentration is low. If the consequent slight turbidity is the same in blank and sample, it is of no importance, if it is not the same, it can be corrected for by reading the tubes also with the red filter #66 and calculating a corrected blank $B_c = B_s \times \frac{X_c}{B_{66}}$

Tracer studies on the biosynthesis of glucuronic acid E H MOSBACH* AND C G KING *Dept of Chemistry, Columbia Univ, New York City*

The utilization of glucose and carbon dioxide for glucuronic acid synthesis in the guinea pig has been investigated using uniformly labeled C^{14} -D-glucose and $NaHC^{14}O_3$. Borneol was administered orally to induce stimulation of glucuronic acid synthesis, and urinary borneol glucuronide was isolated as the zinc salt. After 24 hours, 2 to 4% of the radioactivity of uniformly labeled C^{14} -D-glucose (administered by intraperitoneal injection) was recovered in the urinary glucuronic acid, while only 0.2 to 0.3% of the injected dose was found in the glucuronic acid when $NaHC^{14}O_3$ was used as the source of radio-carbon. Partial degradation of the isolated glucuronic acid indicates that the carbon chain of glucose is available directly for conversion to glucuronic acid. $C^{14}O_2$ appears to enter the glucuronic acid molecule via fixation into glucose and liver glycogen. Injection of 1- C^{14} -L-ascorbic acid into borneol-treated guinea pigs showed that this compound is unavailable for conversion to borneol glucuronide.

Pituitary preparations more potent than electrophoretically homogeneous adrenocorticotrophic hormone (ACTH) PAUL L MUNSON, FRANCES L NAYLOR AND WILLIAM D GRAY (introduced by C N H LONG) *Dept of Pharmacology, Yale Univ, New Haven, Conn*

Because of its high potency, stability, thorough biological evaluation and availability, 'La-1-A', a hog pituitary fraction prepared by Munson in 1944, is accepted as the practical working bioassay standard for adrenocorticotrophic hormone (ACTH). Although La-1-A contains two electrophoretically distinct components it is equal or superior in potency to the homogeneous protein isolated previously by others. Two additional pituitary fractions have been prepared which are approximately twice as potent as pure ACTH, yet neither is electrophoretically homogeneous. Both were obtained from acid acetone extracts of hog pituitaries, the first by the usual methods of salt and pH precipitation. The second was prepared by the application of what is believed to be a new approach in protein fractionation. The ACTH in the crude extract was concentrated by extraction with 0.1 M Na_2HPO_4 , precipitation with $(NH_4)_2SO_4$, and removal of fractions insoluble between pH 9 and pH 4.7. The remaining solution at pH 4.7 contained 5% protein and 5% $(NH_4)_2SO_4$. When two-thirds volume of acetone was added and the mixture chilled below 0° C, the solution separated into two liquid phases, and the bulk of the ACTH activity was found in the lower. In other applications of this procedure,

however, the distribution of the ACTH activity between the two phases has been found to vary with the pH, temperature and relative concentrations of water, acetone, protein and inorganic salt.

Blood phosphorus, calcium, citric acid and total protein after oral administration of calcium hexose phosphate SAMUEL NATELSON,* MARGARET KLEIN* AND BENJAMIN KRAMER *Pediatric Research Lab, Jewish Hospital of Brooklyn, Brooklyn, N Y*

Calcium fructose diphosphate was administered orally (6 gm) in pill form to 10 normal adults. Blood levels of calcium, protein, citric acid, inorganic phosphorus and organic phosphorus not precipitable by trichloroacetic acid were determined on fasting, and at the end of one, 2 and 3 hours. An average rise of approximately 16% of inorganic phosphorus was noted, of 5% in calcium levels, 6.5% in citric acid levels and 1% in protein levels. The most dramatic rise was observed in the levels of non-protein-organic phosphorus, which rose approximately 200% above the fasting levels. Approximately from 8-35% of the organic phosphorus taken orally may be accounted for in the extracellular fluid in combined form as summing uniform distribution. The rise in calcium levels was less than might be expected after the administration of 6 gm of calcium hexose diphosphate. This probably signifies the dissociation of the compound in the intestines with absorption of the fructose-diphosphate radicle independently of the calcium. Similar results were observed with calcium glycerophosphate in one instance and direct absorption of combined phosphate is probably a general characteristic of the phosphoric acid esters of polyhydroxy compounds.

Effects of anions on the activity of carboxypeptidase HANS NEURATH AND GLENN DE MARIA* *Dept of Biochemistry, Duke Univ School of Medicine, Durham, N C*

It was recently reported that the hydrolysis of carbobenzoxyglycyl-L-leucine by carboxypeptidase is inhibited by orthophosphate, pyrophosphate, citrate, oxalate and cyanide (SMITH AND HANSON *J Biol Chem* 179: 803, 1949). From the nature of the inhibitory anions it was concluded that carboxypeptidase is a metal-protein and that magnesium is the essential activating metal ion. Because of the general significance attached to these findings (SMITH *Federation Proc* 8: 581, 1949), the effect of these anions on the enzymatic hydrolysis of the typical substrate carbobenzoxyglycyl-L-phenylalanine was investigated and evaluated in terms of the kinetic constants k_2 and K_m , determined from initial reaction velocities, and also in relation to the reaction course. Ortho-

phosphate, up to 0.2 M, has no effect on k_2 and K_m , nor on the inhibition by D-phenylalanine (K_i). However, beyond the initial phase, the reaction was retarded in 0.2 M orthophosphate, owing to inhibition by L-phenylalanine, as confirmed also by measurements in which L-phenylalanine was added in stoichiometric excess. The orthophosphate effect was instantaneous and reversible. Inhibition by L-phenylalanine was negligible as compared to D-phenylalanine. Similar, though accentuated, effects were obtained with 0.01 M pyrophosphate. Citrate (0.1 M), oxalate (0.1 M) and cyanide (0.002 M) had no measurable effects whatsoever. It is concluded that combination of carboxypeptidase with orthophosphate or pyrophosphate, in itself, does not impair catalytic activity but merely retards the rate of desorption of one of the end products. A specific contribution of magnesium to the catalytic activity of carboxypeptidase is not evident from these findings.

Effect of methionine on toxicity of crystalline 'agene factor' against *Leuconostoc mesenteroides* G. W. NEWELL AND W. W. CARMAN (introduced by L. REINER) *Research Labs of Wallace and Tiernan Products, Inc., Belleville, N. J.*

It has been reported that the crystalline toxic factor obtained from nitrogen trichloride treated zein inhibits the growth of *Leuconostoc mesenteroides*, P-60 (HEATHCOTE *Nature* 161:43, 1949). This has been confirmed with material isolated in our laboratories. The relationship between concentration of toxic factor and percentage inhibition of growth was studied under various conditions. Fifty % inhibition of growth was obtained with 4-6 $\mu\text{g}/\text{cc}$. Methionine reversed the growth inhibition almost completely when its concentration was 12 times that of the toxic material and a detectable reversing effect of methionine still occurred at concentrations equal to that of the toxic material. A number of compounds have been tested to determine whether the effect of methionine is specific. Among sulfur-containing compounds methionine sulfoxide and glutathione showed about 1/10 the activity of methionine, while methionine sulfone produced little reversal of the inhibition. Cystine, cysteine, cysteic acid and homocystine were without any effect. Methyl donors, such as choline, gave no protection.

Preparation, bioassay and metabolism of radioactive 17-methylestradiol H. J. NICHOLAS*, S. A. THAYER, E. A. DOISY, JR.*, WILLIAM H. ELLIOTT*, B. BOCKLAGE* AND EDWARD A. DOISY *Depts. of Biochemistry and Internal Medicine, St. Louis Univ. School of Medicine, St. Louis, Mo.*

A preliminary study has been made of the metabolism of 17-methylestradiol, labeled with car-

bon 14 at the C-17 methyl group. The non-radioactive compound, reported as the 3-methyl ether in crude form by Cohen and Cook (*J. Chem. Soc.* 445, 1935), was prepared from estrone acetate by the reaction with methyl magnesium iodide. The 17-methylestradiol and a derivative were characterized by the customary procedures. A similar procedure using 1 millicurie of $\text{C}^{14}\text{H}_3\text{I}$ produced 17-methylestradiol with activity of 9662 c/m/mg. The free phenol was approximately equal in estrogenic activity to α -estradiol when assayed by 4 different methods. The radioactive compound was injected into normal adult female rats at 10 mg levels. Most of the radioactivity was recovered from the feces over a 72-hour period, with a small amount in the urine. In rats with bile fistulas, the major portion of the radioactivity was recovered from the bile.

Enzymatic degradation of coenzyme A G. DAVID NOVELLI*, NATHAN O. KAPLAN AND FRITZ LIPMANN *Biochemical Research Lab., Massachusetts General Hospital, Dept. of Biological Chemistry, Harvard Med. School, Boston, Mass.*

It was reported previously that intestinal phosphatase inactivates coenzyme A (Co A) and liberates all bound phosphate, with prostate phosphatase, however, which acts exclusively on monoesters, no inactivation of Co A occurs. More recently, the action of a potato dinucleotidase on Co A was studied. Lowry and Colowick observed (unpublished) that between 1.2 and 1.8 M $(\text{NH}_4)_2\text{SO}_4$ concentrations, a fraction was obtained from potato extract which splits diphosphopyridine nucleotide and flavinadenine dinucleotide into the respective mononucleotides. If Co A was incubated with this potato enzyme in conjunction with prostate phosphatase, complete inactivation and liberation of inorganic phosphate occurred. In absence of prostate phosphatase, the action of the dinucleotidase was obscured by the fact that in crude liver extracts, in the presence of ATP, a resynthesis of Co A occurred from the split products. To show inactivation of Co A by dinucleotidase, a purified liver fraction, obtained between 40 and 70% $(\text{NH}_4)_2\text{SO}_4$ saturation, had to be used for the tests on sulfanilamide acetylation. With this assay system, activity disappeared after incubation of Co A with potato enzyme. These experiments seem to suggest a structure for Co A which is similar to that of pyridine and flavinadenine dinucleotide. It is of interest that in Cheldelin's *Acetobacter* growth test, after incubation with dinucleotidase presumably liberating pantothenyl phosphate, Co A shows a 2- to 2.4-fold increase in activity. This seems to support our earlier suggestion that Cheldelin's factors were a degradation product of Co A.

Intracellular distribution of phosphatase activity in rat liver ALEX B. NOVIKOFF, ESTELLE PODBER AND JEAN RYAN (introduced by ELVIN A. KABAT) *Depts. of Pathology and Biochemistry, Univ. of Vermont College of Medicine, Burlington*

Rat liver homogenates, prepared in distilled water and 0.88 M sucrose, were separated by differential centrifugation into 4 fractions: nuclei, mitochondria, sub-microscopic particles and 'supernatant fluid'. Homogenate, fractions, and a mixture of the fractions reconstituting the original homogenate were tested for phosphatase activities with disodium phenyl phosphate (OP) at pH 4.5 and 9.1, adenosine-5-phosphate (A5P) at pH 7.4, and adenosine triphosphate (ATP) at pH 7.4, under conditions in which enzyme activity (micrograms P split from substrate) bears a linear relation both to tissue concentration and to time of incubation. A chart shows the distribution of phosphatase activities in the fractions obtained from water homogenates, expressed in percentage of original homogenate activity.

	P, pH 4.5	P, pH 9.1 $10^{-2}M$ MgCl ₂	A5P, pH 7.4 $3 \times 10^{-2}M$ MgCl ₂	ATP, pH 7.4 $10^{-2}M$ MgCl ₂
Nuclei ¹	5-10%	10-18%	40-45%	10-20%
Mitochondria	35-40	17-20	40-45	70-75
Sub-microscopic particles	5-10	0-10	5-10	2-4
'Supernatant fluid'	35-50	55-70	10-15	0-1
Mixture	90-100	85-105	85-105	85-105

¹ Contaminated with unbroken cells and mitochondria.

The intracellular distribution of activities is the same in 0.88 M sucrose homogenates as in water homogenates in the case of OP at pH 4.5 and 9.1, but significant differences occur with A5P and ATP. Other data to be presented for each fraction include 1) phosphatase activities with A5P and ATP in the presence of CaCl₂, 2) nucleic acid (DNA, PNA) and nitrogen content and 3) succinoxidase activities.

Nucleic acids in development and division of plant cells MAURICE OGUR AND RALPH O. ERICKSON (introduced by WAYNE UMBREIT) *Botanical Labs, Univ. of Pennsylvania, Philadelphia*

A quantitative study of the nucleic acids during development and mitotic division has been made based upon further extensions of assay methods previously reported (OGUR AND ROSEN *Federation Proc.* 8:234, 1949; *Arch. Biochem.* In press). Suspensions of microsporocytes, microspores and

pollen grains from anthers of *Lilium longiflorum* have been prepared. Cell numbers have been counted and cell homogenates have been analyzed for pentose nucleic acid (PNA) and desoxypentose nucleic acid (DNA). Analytical results have been calculated to the nucleic acid content per cell. These results have been related to the logarithm of flower bud length, which serves as an external time index of the developmental and cytological status of the cells (ERICKSON *Am. J. Bot.* 35:729, 1948). This report covers the developmental period from microsporocyte meiosis to pollen release. A sharp drop in DNA content per cell is observed at meiosis followed by a gradual linear increase during the interphase of microspore development. Just prior to microspore mitosis DNA content doubles rapidly. The resulting binucleate pollen grain shows a further increase in DNA content with time before the pollen is normally released from the flower. The PNA content follows the same pattern up to microspore mitosis at a level about twice that of DNA, increases sharply at mitosis, and continues to increase rapidly at a rate nine times that for DNA in the maturing pollen grain.

New coenzymes of cell-free fermentation PAUL OHLMEYER (introduced by ARTHUR KORNBERG) *National Insts. of Health, Bethesda, Md.*

Previous investigations showed that the glucose fermentation in dialyzed *Lebedewsaft* is stimulated by a thermostable fraction prepared from fresh yeast (*Ztschr. f. physiol. Chem.* 267:264, 1941). It contained 2 factors and could not be replaced by known coenzymes including adenosinetriphosphate. Further studies have now led to the observation that the fraction maintains a high rate of fermentation even after the inorganic phosphate is exhausted, contrary to the Harden and Young equation. The velocity is constant and near maximal as long as free sugar is available, thus, the addition of inorganic phosphate or arsenate does not even double the rate and phosphopyruvic acid does not influence it at all. This effect which appears related to the transfer or liberation of phosphate is not due to activation of adenosinetriphosphatase; the fermentation of hexosediphosphate or phosphopyruvic acid in the absence of glucose is not accelerated by the thermostable yeast fraction. Purification of the fraction showed that one of the factors (A) is very similar to or identical with the adeninedinucleotide of Meyerhof and Kiessling (*Biochem. Ztschr.* 296:410, 1938). While factor A alone acts as a transphosphorylating coenzyme it does not give the fermentation effect described above in the absence of the second factor. The nature of the coenzyme factors and the mechanism of their action are under investigation.

Comparative metabolism of radioactive glucose in heart, brain, kidney and liver slices ROBERT E OLSON, JAMES S ROBSON, HEIDI RICHARDS AND EMILY G HIRSCH (introduced by HALVOR N CHRISTENSEN) *Dept of Nutrition, Harvard School of Public Health and Dept of Biological Chemistry, Harvard Med School, Boston, Mass*

Glucose utilization by slices of heart, brain, kidney, and liver from representative mammalian (rat, rabbit, guinea pig, cat) and avian (duck, pigeon) organisms was studied with the aid of radioactive glucose prepared photosynthetically. Tissue slices were incubated in Warburg vessels at 37°C with C^{14} -labeled glucose at concentrations ranging from 1.25 to 20 mM/l for one hour. Glucose disappearance or appearance and aerobic glycolysis were determined chemically, and the rate of oxidation of added glucose determined by counting the $C^{14}O_2$ captured in the center well. Oxidation of glucose to CO_2 occurred in all tissues but at vastly different rates. $C^{14}O_2$ production from added glucose in mammalian liver was of a very low order ($QC^{14}O_2 = ca\ 0.1$) as indicated previously in a comparison with hepatoma (*Proc Am Chem Soc* 116:61C, 1949). Oxidation rates were 15–20 times as rapid in heart, avian liver, and kidney slices, and 60–100 times as rapid in brain slices. Increasing initial glucose concentration uniformly resulted in increased oxidation rates. In all cases, except with livers rich in glycogen, disappearance of glucose exceeded oxidation rate by several-fold. Neither glycogenolysis nor glycogenesis in liver slices appeared to affect the rate of oxidation of added glucose. Aerobic glycolysis accounted for part of the glucose which disappeared and bore a positive relationship to the rate of $C^{14}O_2$ production. Studies of anaerobic glycolysis in homogenates of duck and rat liver with various physiological hexose phosphates as substrate suggest that the activity of phosphohexokinase may be the limiting factor in breakdown of glucose by mammalian liver.

Preparation of thymus nucleohistone in native form GERALD ORGEL* AND KURT G STERN
Dept of Chemistry, Polytechnic Inst of Brooklyn, N Y

The isolation of a desoxyribonucleoprotein from calf thymus with the aid of desoxyribonuclease inhibitors and aqueous solvents of low ionic strength has been briefly reported (*Federation Proc* 6:296, 1947). It has since been found that this material exhibits significant ATP-ase activity (114th Meeting, A C S, Wash, D C, 1948). The isolation procedure has been modified to improve its reproducibility and the uniformity of the nucleoprotein preparations. The new method involves the following steps: removal of cytoplasmic proteins from thymus homogenates

by exhaustive extraction with 0.14 M NaCl at 0°C, extraction of the desoxyribonucleoprotein from the nuclear residue with 20% ethanol at -5°C, precipitation of the nucleoprotein with acetate buffer, pH 4.6, at 0°C, dissolving the precipitate in phosphate buffer, pH 7.4, of low ionic strength, reprecipitation of the nucleoprotein with 0.14 M NaCl at 0°C, and redissolving the nucleoprotein in distilled water or phosphate buffer, pH 7.4, of low ionic strength to form colorless, opalescent sols. The final product may be preserved as a white, fluffy, soluble material by freeze-drying. The DNA-content (Dische Reaction) approximates 20%. The nucleoprotein contains arginine (Sakaguchi Reaction) and forms a stable, insoluble complex with lanthanum salts at pH 7. The sedimentation and electrophoretic behavior of the nucleohistone preparations, as well as their viscosity, flow birefringence, infrared and ultraviolet light absorption, and enzymatic activity towards energy-rich phosphate compounds are described.

Application of partition chromatography to study of absorption of amino acids from the intestine

ALINE UNDERHILL ORTEN, C J FRANCE AND K KIOZUMI (introduced by ARTHUR H SMITH)
Depts of Surgery and Physiological Chemistry, Wayne Univ College of Medicine, Detroit, Mich
Employing the starch column chromatographic technic (STEIN AND MOORE *J Biol Chem* 176:337, 1948; MOORE AND STEIN *J Biol Chem* 176:367, 1948), the first 4 emerging amino acids, leucine, isoleucine, phenylalanine and methionine, have been studied. The results of Stein and Moore in which approximately 0.1 mg quantities of each of the 4 amino acids are separated and recovered quantitatively from pure solution have been confirmed. The identical mixture of these amino acids in the same amounts have been separated quantitatively from intestinal loop contents with the same degree of accuracy. A method for removing protein and other contaminants which may interfere in the determination of amino acids by the ninhydrin reaction has been developed. Thiry jejunal loops of dogs were prepared by the method of Johnston (*Proc Soc Exper Biol & Med* 30:193, 1932). Water was placed in the loop, the loop contents withdrawn after an hour, and the samples prepared for chromatographic analyses in such a way that a flat base line chromatogram showing no effluent peaks was obtained. Leucine placed in such loops and immediately withdrawn and determined by the above procedure is consistently recovered. Studies of the comparative absorption rates of leucine, isoleucine and phenylalanine from Thiry loops are reported.

Ergosterol synthesis in neurospora R C OTTKE*, E L TATUM, I ZABIN* AND K. BLOCH *Dept of Chemistry, Yale Univ, New Haven, Conn, Dept of Biology, Stanford Univ, Calif, and Dept of Biochemistry, Univ of Chicago, Chicago, Ill*

The synthesis of ergosterol has been studied in a *Neurospora* mutant which requires acetate for growth. The mold was grown on a medium which contained sucrose, 15 gm and doubly labeled acetate ($C^{14}H_3C^{18}OOH$), 5 gm. Calculated on the basis of a C^{13} concentration of 100 and a specific activity for C^{14} of 100 in the added acetate, the isotope concentrations were 20 in the mold mycelium and 60-70 in the ergosterol isolated from the cells. Acetate is therefore a preferential carbon source for the mold steroid as previously demonstrated with deuterioacetate (OTTKE, TATUM AND SIMMONS, *Federation Proc* 8 235, 1949). In a second experiment the acetate-less strain of *Neurospora* was grown on a medium containing sucrose, 15 gm, acetate, 5 gm, and a small quantity of isotopic isovaleric acid. The labeled substrate contained C^{13} in the end methyl groups and C^{14} in the carboxyl group. The isotope concentrations in the mycelium and in ergosterol were less than 1% of those in the isovalerate, indicating either that isovalerate was not appreciably metabolized or that isovalerate carbon was greatly diluted by carbon from other sources. It was found however that the C^{13} concentration was 5 times greater in ergosterol than in the mycelium, while the C^{14} concentrations of both mycelium and of the sterol were negligible. Therefore, in the synthesis of ergosterol by *Neurospora* as well as of cholesterol by the rat (ZABIN AND BLOCH, *Federation Proc* 8 267, 1949) the isopropyl moiety of isovalerate is a more efficient source of carbon than the carboxyl portion of the molecule.

Diamine oxidase in streptomycin sensitive and resistant strains of *Mycobacterium smegmatis*

C A OWEN AND E A ZELLER (introduced by M H POWER) *Division of Biochemistry, Mayo Foundation, Rochester, Minn*

Previous studies indicated that the diamine oxidase (DO) of *Mycobacterium tuberculosis* var *hominis* is sensitive to less than 10^{-5} M dihydrostreptomycin. The DO of sensitive strains of *Mycobacterium smegmatis* is nearly completely blocked by 10^{-4} M dihydrostreptomycin, while the same concentration does not influence the same enzyme of the corresponding streptomycin resistant strain (ZELLER, E A, C A OWEN AND A G KARLSON, *Proc Staff Meet, Mayo Clin* 24 490, 1949). The question arises as to whether this loss of enzymic sensitivity toward dihydrostreptomycin is due to a change in the physicochemical structure of the DO or to factors apart from the enzyme. The observation that the DO of sensitive

and resistant bacteria is equally sensitive toward pyocyanin, chloramphenicol and streptothricin, points more toward the second alternative. The DO of resistant smegma bacteria, after their brief treatment with acetone, is much more sensitive toward dihydrostreptomycin than before treatment. On the other hand, when sensitive bacteria are incubated with putrescine (which was used in all these studies as the DO substrate), and then washed, they become resistant, even 10^{-3} M dihydrostreptomycin is no longer able to inhibit completely the DO of these pretreated bacteria. Thus the sensitivity of DO of smegma bacteria can be altered by various procedures. A tentative hypothesis to explain these phenomena will be presented.

Studies on the metabolism of pyrimidine ribosides L M PAEGE* AND F SCHLENK *Dept of Bacteriology, Iowa State College, Ames*

Cytosine riboside and uracil riboside are rapidly metabolized by bacterial enzymes. Cytidine is deaminated, nucleoside phosphorylase splits off the base, and rapid disintegration of the carbohydrate occurs as described earlier for purine ribosides (SCHLENK, F *Adv Enzymol* 9 455, 1949). No indication was found that the action of bacterial pyrimidine nucleoside phosphorylase is preceded by opening of the pyrimidine ring as suggested by Mitchell and Houlahan for *Neurospora* (*Federation Proc* 6 506, 1947). For determination of pyrimidine-bound ribose the ordinary orcinol technique is not suitable. A modification has been elaborated which permits distinction between pyrimidine nucleosides and other pentose derivatives.

Effect of growth hormone on the glucose uptake and glycogen synthesis by the rat diaphragm

C R PARK AND WILLIAM H DAUGHADAY (introduced by M E KRAHL) *Dept of Biological Chemistry, Washington Univ School of Medicine, St Louis, Mo*

Glucose uptake by rat diaphragm *in vitro* and the effect of added insulin diminish rapidly during 2 hours of incubation. Using pooled sections of diaphragms from 6 rats suspended in Krebs-Henseleit medium containing 140 mg % glucose, the rates of glucose uptake (mg/gm wet tissue/hour for the first 30-min period) were as follows: normal rats 3.2, hypophysectomized rats 5.0, hypophysectomized - adrenalectomized rats 4.7, with insulin added *in vitro* normal 6.7, hypophysectomized 6.5, hypophysectomized - adrenalectomized 6.9. Crystalline growth hormone of high growth potency injected intraperitoneally into hypophysectomized rats reduced glucose uptake to normal. This effect was obtained 24 hours after one injection of 20 γ per 100 gm of rat or after repeated injections of 5 γ daily. Adrenal-

cortical extract or ACTH did not depress glucose uptake under the conditions tested. In hypophysectomized - adrenalectomized rats growth hormone led to less depression of glucose uptake than in hypophysectomized rats unless adrenal cortical extract was injected concurrently. The initial glycogen content of diaphragm from hypophysectomized rats fasted 24 hours was not altered significantly by growth hormone or adrenal cortical extract injection. Initial glycogen in diaphragm of hypophysectomized - adrenalectomized rats was very much higher than in diaphragm of hypophysectomized or normal rats. Glycogen synthesis was proportional to glucose uptake in all these cases and corresponded to about half of the glucose utilized.

Isolation of three labile phosphate compounds containing uracil from penicillin-treated *Staphylococcus aureus* cells JAMES T. PARK (introduced by MARVIN J. JOHNSON) *Camp Detrick, Frederick, Md.*

The accumulation of acid-soluble, labile phosphate in *S. aureus* cells during growth in the presence of 0.5 unit of penicillin per ml. has been reported (PARK, J. T. AND M. J. JOHNSON, *J. Biol. Chem.* 179: 585, 1949). Purified preparations rich in labile phosphate (10-min. hydrolysis in 1 N HCl at 100° C.) were obtained by alcohol precipitation of the barium salts and use of the cation exchange resin, IR100. The material was resolved into 3 components by use of partition chromatography (mobile phase: phenol, non-mobile phase: 0.1 M sulfate buffer, pH 1.7). Each of the separated components contained, in approximately equimolar proportions, uracil, labile phosphate, stable phosphate, pentose (orcinol test), and an unknown sugar. Preparations of the component most soluble in phenol gave positive biuret tests. This component contains approximately 3 moles of alanine per mole of labile phosphate, and it may contain 1 mole of glutamic acid. The second component, which is believed to be a mixture of 2 labile phosphate compounds, contains alanine. The third component contains no amino acids. The amino acids have been tentatively identified by paper chromatography employing 82% phenol as the solvent. It is suggested that this series of complex molecules may be normal intermediates of the cell and that the inhibition of a specific synthetic reaction by penicillin causes them to accumulate in abnormal amounts.

Interaction of quinoline and acridine derivatives with nucleoproteins and nucleic acids FRANK S. PARKER,* J. LOGAN IRVIN AND ELINOR MOORE IRVIN * *Dept. of Physiological Chemistry, Johns Hopkins Univ. School of Medicine, Baltimore, Md.*

A recently reported study (*Science* 110: 426,

1949) of the reversible interaction of antimalarials of the 4-aminoquinoline and 9-aminoacridine series with nucleic acids has been extended to nucleoproteins. The cationic species of quinacrine, of 7-chloro-4-(1'-methyl-4'-diethylaminobutylamino)-quinoline (SN-7618) and of 2-methoxy-6-chloro-9-(1'-methoxyl-8'-diethylamino octylamino)-acridine (SN-12868) interact strongly with a highly polymerized, asymmetric desoxy-pentose-nucleoprotein of spleen. For the interaction with this nucleoprotein the values of log *k* (the association exponent, formulated as described previously for the case of interactions with nucleic acids) are 3.7 for SN-7618 and 4.3 for SN-12868 at pH 6 and ionic strength 0.02. At ionic strength 1.0 the value of log *k* is 2.8 for SN-12868, thus demonstrating that the effect of ionic strength on the interaction with nucleoprotein is comparable with the large effect previously reported in the study of nucleic acids. Each of these antimalarials interacts with the nucleoprotein more strongly than with a less highly polymerized preparation of pentose-nucleic acid from yeast. All interactions were evaluated spectrophotometrically at concentrations of the nucleoprotein (0.5 to 10 µg. of nucleoprotein-phosphorus per ml.) and of the antimalarial compound (5×10^{-5} M) at which the complex remains in solution. At higher concentrations (5×10^{-4} M, and greater) of the antimalarial compounds precipitation of the complex occurs. The compound, 2-methoxy-6-chloro-9-aminoacridine, also interacts strongly with nucleoprotein, which suggests that the side-chains of quinacrine and SN-12868 are not essential for the interactions although the side-chains modify other properties, such as solubility, to an important degree.

Electrophoretic analyses of plasma and serum proteins in rheumatoid arthritis and rheumatoid spondylitis W. D. PAUL* AND JOSEPH I. ROUTH *Dept. of Medicine (Div. of Physical Medicine) and Biochemistry, College of Medicine, State Univ. of Iowa, Iowa City*

One hundred and twenty-two plasma and serum samples were obtained from 70 patients with arthritis. Included in this series were plasma-serum pairs from 34 patients. These samples were diluted with 3 volumes of barbiturate buffer (pH 8.6), dialyzed 3 days at 5° C. and subjected to electrophoresis in the Tiselius apparatus. The analytical cell was used. The plasma proteins of 57 patients with rheumatoid arthritis showed a marked decrease in albumin, a marked increase in fibrinogen and γ globulin, and a moderate increase in α_1 and α_2 globulin components when compared to plasma from normal individuals. Ten children, under 15 years of age, with this disease, showed a greater decrease in plasma albumin and increase in γ globulin than the adults. An

analysis of plasma-serum pairs from 27 adults in this group gave values similar to those obtained with plasma. The average γ' globulin content of the serum was 3.0%, which is a normal value. A group of 7 patients with rheumatoid spondylitis showed strikingly different plasma and serum patterns from rheumatoid arthritis. Average values for all components fell within the range for normal individuals. The γ' globulin component in the sera averaged 1.9%. Other types of arthritis including osteo or degenerative arthritis are being studied.

Isolation of cell nuclei in neutral medium MARY L. PETERMANN AND ROSE M. SCHNEIDER *Sloan-Kettering Inst. New York City*

The great elevation in total pentose nucleic acid (PNA) found in the spleen of the leukemic mouse is caused by increases in the PNA content of both the cytoplasm and crude 'nuclear fraction' (*Cancer* 2:510, 1948). In order to determine the PNA content of the nuclei alone an isolation procedure which would avoid contamination with cytoplasmic nucleoprotein was required. This has been accomplished in a neutral medium containing 0.88 M sucrose and approximately 0.002 M CaCl_2 . The entire procedure was carried out at 4° C. One gram of fresh mouse spleen was crushed in a glass homogenizer in 15 cc. of sucrose. It was then strained successively through surgical gauze, single-napped flannelette, and double-napped flannelette, into a 50 cc. centrifuge tube. The contents were homogenized by means of a stirrer consisting of stainless steel blades rotating at 16,000 r.p.m. The homogenate was centrifuged for 10 minutes at $600 \times g$ and the sediment washed three times. The final sediment was resuspended to give approximately 10^8 nuclei/cc. and counted in a haemocytometer. Wet smears stained with methyl green-pyronin or orcein-fast green (KURNICK AND RIS, *Stain Technol.* 23:17, 1948) showed well dispersed and morphologically intact nuclei, free from microscopically evident cytoplasmic material. Their content of nitrogen and of both types of nucleic acid has been determined.

Net production of serum albumin in vitro THEODORE PETERS, JR. AND CHRISTIAN B. ANFINSEN *Biophysical Lab and Dept. of Biological Chemistry, Harvard Med. School, Boston, Mass.*

Serum albumin content of a chicken liver slice system was found to increase from about 0.3 mg/gm. liver to 0.6-1.0 mg/gm. in a 5-hour incubation in O_2 , but only to 0.35-0.4 mg/gm. in N_2 . These results lend direct confirmation to previous conclusions (PETERS AND ANFINSEN *J. Biol. Chem.* 182: No. 1, In press) regarding serum albumin synthesis based on measurements of the *in vitro* incorporation of radioactive CO_2 . Serum albumin was determined by a quantitative immunochem-

ical precipitin technique, using rabbit antiserum against serum albumin of over 99% electrophoretic purity prepared from chicken serum. A standard curve relating the amount of precipitate formed to the amount of antigen added was determined. Aliquots of the combined homogenized slices and medium were analyzed for serum albumin content after centrifugation. The initial serum albumin level was lowered by perfusion of the intact liver and by washing the slices in medium for an hour prior to the experiment. The bulk of the serum albumin present after 5 hours was in the medium. Studies were also made on the effects of ions, substrates, and inhibitors. Calculations based on the observed rates of production indicate that the liver could replace half the circulating serum albumin of the intact animal in 5-8 days.

Characteristics of the amino acid incorporation system of liver homogenates ELBERT A. PETERSON,* DAVID M. GREENBERG AND THEODORE WINNICK *Div. of Biochemistry, Univ. of California Med. School, San Francisco*

The incorporation of carboxyl and α -labeled glycine, phenylalanine- $\beta\text{-C}^{14}$, serine- $\beta\text{-C}^{14}$ and methionine- $\text{CH}_3\text{-C}^{14}$ into protein has been studied, using a suspension of cytoplasmic granules obtained by fractional centrifugation in a $\text{KCl} - \text{KHCO}_3$ medium. The incorporation activity of the cytoplasmic granules, which was relatively low alone, was increased as much as seven-fold by mixing it with the supernatant from a concentrated (1:1) homogenate centrifuged at 2700 g or with a medium containing ATP, Mg^{++} , citrate, and a mixture of a number of L-amino acids, except with methionine. When ATP was omitted, the incorporation was even lower than with no additions. With methionine, only ATP was activating. In the presence of the above-mentioned activators, plus phosphoglycerate, a particle free supernatant (20,000 g) can incorporate the label of glycine aerobically, but not anaerobically. The radioactive protein obtained with radio-glycine loses a considerable portion of its label when treated with mercaptoethanol or with performic acid evidently as a result of the cleavage of disulfide bonds. This is true for whole liver homogenates also but not for protein from embryo homogenates or tissue slices. The removed radio material may possibly be glutathione but this has not yet been positively identified. When the label is methionine- $\text{CH}_3\text{-C}^{14}$, most of the radioactivity is removed by mercaptoethanol and protein labeled with radio serine loses a small amount of activity on such treatment. However, the radio activity of protein incubated with phenylalanine $\beta\text{-C}^{14}$ is completely resistant to both reagents.

Pyrimidine content of certain pentose and desoxy-pentose nucleic acids ANTHONY PIRCIO* AND

LEOPOLD R. CERRERO *Dept of Biochemistry, Fordham Univ., New York City*

A colorimetric method for the determination of cytosine and uracil, developed in this laboratory (*J Biol Chem* 181 713, 1949) has been applied to a study of the distribution of the free pyrimidines, the pyrimidine nucleosides and nucleotides of the pentose nucleic acids of yeast, dog liver, and wheat germ. The separation of cytosine and uracil was carried out by means of the zeolite, Decalco, while cytidine and uridine could be separated with the aid of the resin, Zeo-Rex. The pyrimidine composition of both the yeast and wheat germ pentose nucleic acids was found to be closely similar, but that of the dog liver differed in that approximately twice as much cytosine as uracil was found. Although the yeast and wheat germ pentose nucleic acids contained nearly equal amounts of the free pyrimidines and of the pyrimidine nucleosides, the quantities found were not as high as would be expected from the tetranucleotide hypothesis. For the determination of thymine, a method based on Hunter's qualitative test (*Biochem J* 30 745, 1936) has been developed. While this work was in progress, Woodhouse (*Biochem J* 44 185, 1949) published a method which is based on the same principle. Using this procedure in conjunction with the aforementioned method for the estimation of cytosine, thymine and cytosine were determined in the hydrolysates of the desoxy-pentose nucleic acids of fish sperm and calf thymus. The molar ratios of thymine to cytosine found were for fish sperm DNA, 1.2:1, for calf thymus DNA, 1.6:1.

Quantitative histochemical distribution of enzymes in cytoarchitectural layers of cerebral cortex. ALFRED POPE, JAMES R. WARE, AND RUBY H. THOMSON (introduced by J. FOLCH) *McLean Hospital, Waverley, Mass. and Harvard Med School, Boston, Mass.*

In the nervous system the mutual interdependence of structure and function makes the correlation of chemical composition with histological structure of especial importance. Because of its laminated architecture the cerebral cortex is suitable for such correlative study by the methods of quantitative histochemistry (LINDERSTRÖM-LANG, *K. Harvey Lect* 34 214, 1939). Accordingly, techniques for alternate frozen section sampling, histological control, and ultra-micro enzyme assay are being used to establish the quantitative distribution of certain enzymes within the cytoarchitectural layers of rat somatosensory isocortex. Enzymes of probable importance in the general or special metabolism of the nervous system are thus being studied, and attempts made to correlate their distribution patterns with details of the histological fine structure of this region. Thus,

diphosphopyridine nucleotide and alanyl-glycine dipeptidase have been found most abundant in layers II, IIIB-IV, and VC-VIA (designations of Brodmann) which are levels numerically rich in ganglion cells, thereby suggesting that these substances are mainly located within nerve cell bodies together, perhaps, with their protoplasmic expansions. Similarly, acetylcholinesterase and adenosinetriphosphatase (preliminary experiments) have been found most active in layers I, IIIA, IIIB, and VA-VB. These are levels within or just superficial to zones containing many horizontal myelinated fibres and are probably regions of extensive fine arborization of axons and hence of maximal axonal surface. It is suggested, therefore, that in cerebral cortex as in peripheral nerves these enzymes may be principally located at axonal surfaces.

Effect of fluoroacetate on reactions in the Krebs oxidative cycle. VAN R. POTTER AND HARRIS BUSCH * *McArdle Memorial Lab., Med School, Univ of Wisconsin, Madison.*

Buffa and Peters reported in 1949 that injections of lethal doses of fluoroacetate produced striking increases in the citrate content of brain, heart and kidney and questioned earlier reports that fluoroacetate interfered with acetate metabolism. We have confirmed their findings using 5 mg of fluoroacetate per kg body weight in rats. After one hour the citrate content of these organs was 212, and 1029 $\mu\text{g/gm}$ of wet weight, respectively, while in uninjected animals the citrate content was only about 50 $\mu\text{g/gm}$. The citrate content increased over 2 successive 30-minute periods but ceased thereafter. In addition to the three organs previously studied, increases in all of the other normal organs of the body have been found with the exception of blood and liver. Studies with homogenates showed that liver is capable of producing large amounts of citrate *in vitro*. However, fluoroacetate appeared to divert pyruvate metabolism into acetoacetate formation rather than to cause an increase in citrate in contrast to the results with kidney, in which the alternative pathway is weak or absent, and in which citrate accumulates both *in vivo* and *in vitro*. The results with liver *in vitro* thus seem to explain the lack of citrate production *in vivo*.

Alternative metabolic pathways in rat liver homogenates. VAN R. POTTER AND RICHARD O. RECKNAGEL * *McArdle Memorial Lab., Med School, Univ of Wisconsin, Madison.*

Lehninger previously demonstrated 2 co existing alternative metabolic pathways open to pyruvate in washed residues of liver, one leading to acetoacetate, the other to citrate. In the present study an assay system was devised to determine the relative activities of the two systems in whole

homogenates of rat and mouse liver. Measurements are based on determinations of pyruvate removal and acetoacetate formation. Under optimum conditions for the citrate pathway, i.e., in the presence of adequate quantities of oxalacetate, the pyruvate accounted for as acetoacetate was found to be only 10% of the total pyruvate oxidized, thus demonstrating the high priority of the citrate pathway. However, with no available oxalacetate, pyruvate is quantitatively converted to acetoacetate. Acetoacetate production is therefore a measure of the availability of oxalacetate in this system. This fact forms the basis for studying a related pair of alternative pathways. When ammonium chloride was added to the pyruvate system in the presence of catalytic levels of C_4 acids their regeneration via the Krebs cycle was prevented and acetoacetate production was decreased by an amount equivalent to the C_4 acid originally added. Furthermore, in the ammonium chloride system, pyruvate preferentially forms citrate so long as C_4 acids are present, but is diverted to acetoacetate production as soon as the supply of C_4 acid is exhausted. The ammonium chloride was effective at physiologically significant levels and is believed to divert α -ketoglutarate to glutamate. Ammonium chloride is more effective in blocking regeneration of added C_4 acid than is malonate.

Enzymatic resolution of racemic histidine, cystine, and alanine VINCENT E. PRICE,* LEON LEVINTOW* AND JESSE P. GREENSTEIN *Natl. Cancer Inst., Natl. Inst. of Health, Bethesda, Md.*

Although most of the racemic amino acids can be easily resolved by asymmetric enzymatic hydrolysis of their N-acylated derivatives, histidine, arginine, cystine, and proline are not resolvable by this method. Since one of the reasons for acylation of the amino acids is to remove their dipolar character, it was considered that this could be accomplished as well by amide formation. Consequently, DL-histidine amide, S-benzyl-DL-cysteine amide, and DL-alanine amide were prepared and subjected to the action of hog kidney or liver concentrates at pH 8.8-9.2. The concentrates were prepared by low temperature-alcohol fractionation of the tissue homogenates. Mn^{++} in a final concentration of 0.01 M was used in the digestion of the former two substrates. The racemates were hydrolyzed asymmetrically to a mixture of L-amino acid, ammonia, and D-amino acid amide. After removal of the L-amino acid from the deproteinized digest, the mixture was concentrated, brought to pH 11, the D-amide extracted into acetone, the solvent removed, the amide hydrolyzed with dilute HBr, and the free D-amino acid isolated after neutralization. The isomers were obtained in good yield and possessed rotation

values which compared favorably with those in the literature. DL-Proline amide was almost completely resistant to the animal enzymes studied, but both isomers were readily hydrolyzed by mushroom preparations.

Sedimentation and diffusion of *E. coli* bacteriophage T₆ FRANK W. PUTNAM AND EUGENE GOLDWASSER* *Dept. of Biochemistry, Univ. of Chicago, Chicago, Ill.*

The sedimentation and diffusion behavior of *E. coli* bacteriophage T₆ was investigated in the analytical ultracentrifuge and in a refractive index apparatus in a study of the molecular homogeneity, physical constants, and apparent size of this tadpole shaped virus. Although the phage sediments with a single sharp boundary ($S_{20} = 1050S$) at pH 4.9 to about 6.5, a second more slowly sedimenting boundary ($S_{20} =$ about 850 S) is observed at higher pH. The proportion of the two components depends on the age and history of the preparation but is independent of the gravitational field and concentration and is unrelated to the infectivity. Since S_{20} is constant within experimental error from 715g to 18,900g, the particles are unoriented in sedimentation. The virus obeys the laws of normal diffusion, and, at pH 5.5, D_{20} is 0.45×10^{-7} cm²sec⁻¹ for phage which is homogeneous in electrophoresis and in the ultracentrifuge. Equivalent spherical diameters calculated from diffusion (94 μ), from biological infectivity (98 μ), and from sedimentation (60 μ) are in fair agreement with the dimensions previously obtained directly from electron micrographs (head = 60×80 m μ , tail = 100×20 m μ). The particle weight calculated from S_{20} and D_{20} is 1.7×10^8 gms per mole. The results appear to exclude motility for this tailed bacteriophage. Estimates of shape based on S_{20} and D_{20} suggest that the slowly sedimenting form is the monomer and the fast form is a dimer with particles aligned end-to-end.

Effect of surface on coagulation reactions

ARMAND J. QUICK *Dept. of Biochemistry, Marquette Univ. School of Medicine, Milwaukee, Wis.*

A glass surface influences coagulation in a two-fold manner: it causes platelets to adhere and to undergo lysis, and it plays an essential role in the conversion of prothrombinogen to active prothrombin. No adequate explanation for the action of surface on platelets has been offered. Paraffin, silicone and certain plastics having non-wettable surfaces preserve platelets, but collodion which has a wettable surface likewise is equally efficient as a preserver. Since there is good evidence that thrombin is the specific agent responsible for the lysis of platelets, a probable explanation for the paradoxical behavior of collodion can be offered.

A rough surface such as glass has no effect on platelets *per se*. It acquires this property under circumstances which permit the formation of thrombin. It can be postulated that thrombin is adsorbed to a wettable surface and that this layer is responsible for the disintegrating action on platelets. Collodion which not only adsorbs but also absorbs thrombin fails to become coated with a continuous film, therefore platelets coming in contact with its surface do not suffer destruction. The absorption of thrombin by collodion can readily be demonstrated by testing the potency of a standard thrombin before and after contact with collodion. A distinct diminution of activity occurs. The activation of prothrombinogen which is mediated through a rough surface such as glass requires neither thrombin, thromboplastin, calcium nor platelets. The action occurs slowly in ovalated or citrated plasma and rapidly in native plasma, irrespective of the number of platelets.

Glyoxalases E. RACKER, *Dept. of Microbiology, New York Univ. College of Medicine and College of Dentistry, New York City*

In the presence of reduced glutathione, tissue extracts convert methyl glyoxal to lactic acid. Yamazoye using rabbit liver extracts presented evidence for a biologically formed addition compound between reduced glutathione and methyl glyoxal which is not identical with the chemically formed addition compound. This finding has been confirmed in the present study and an enzyme obtained from baker's yeast which catalyzes the formation of the 'biological' addition compound. This enzyme, referred to as glyoxalase I, has been purified by acetone and ammonium sulfate fractionation. When glyoxalase I is added to methyl glyoxal and glutathione, an increase in absorption in the ultraviolet at λ 240 m μ can be observed, which is proportional to the concentration of enzyme added. This is a convenient method for the assay of glyoxalase I. The enzymatic formation of the intermediate compound is proportional to the concentration of both glutathione and methyl glyoxal. Glyoxalase I is used for the preparation of the addition compound which is isolated as an alcohol insoluble barium salt. A second enzyme which catalyzes the breakdown of the intermediate addition compound to lactic acid and glutathione has been purified from beef liver. The activity of this enzyme is measured spectrophotometrically by the disappearance of the absorption of the intermediate. The initial rates are proportional to the enzyme concentration. This enzyme is referred to as glyoxalase II. When purified glyoxalase I and II are combined, a very active glyoxalase preparation is obtained which catalyzes the conversion of methyl glyoxal to lactic acid. This preparation is a sensitive system for the assay of

glutathione since as little as 5 μ g are readily determined.

Analgesic action of 3-hydroxy-N-methyl morphinan hydrobromide (Nu-2206) LOWELL O. RANDALL AND G. LEHMANN, *Pharmacology Dept., Hoffmann-La Roche Inc., Nutley, N. J.*

Nu-2206 is a synthetic substitute for morphine. Structurally, it lacks only the ether-oxygen bridge of dihydrodesoxy morphine-D. The analgesic activity was measured as the percentage increase in reaction time to a radiant heat stimulus applied to the back of rats. By the subcutaneous route, Nu-2206 was found to be 4 times as strong as morphine and about twice as long in duration. By the oral route, Nu-2206 was slightly stronger than Methadon and longer in duration. Tolerance to the analgesic effects developed at about the same rate as with morphine. The response to a constant daily *s.c.* dose decreased about half in a period of 8 weeks and to the limit of error of the method in 11 weeks. Respiration of unanesthetized rabbits was decreased by doses of Nu-2206 which were about $\frac{1}{4}$ those of morphine and the duration was also longer. The compound was spasmogenic to the dog intestine as measured in a Thiry Vella loop but was nearly inactive on isolated rabbit intestine. Nu-2206 is 5 to 6 times as toxic as morphine in several species but about half as toxic as Methadon. Toxic doses produced characteristic morphine effects in animals including tail erection in mice, excitement in cats, depression in dogs and catatonia in rats. The safety factor is slightly less than that for morphine but at least twice that of Methadon. The L-form of the racemic mixture, Nu-2206, has twice the analgesic activity and respiratory depressant action of the DL-mixture and equal toxicity.

Correlation of reductimetric and turbidimetric methods of hyaluronidase assay MAURICE M. RAPPORT,* KARL MEYER AND ALFRED LINKER,* *Dept. of Medicine, Columbia Univ. College of Physicians and Surgeons, New York City*

The mechanism of action of hyaluronidase on hyaluronic acid is not well defined. Of the changes measured to provide estimations of hyaluronidase activity, only the increase in reducing sugar is unambiguously interpretable in a mechanistic sense. The reducing sugar results from the breaking of glucosidic bonds between N-acetyl-hexosamine and glucuronic acid residues. It is further agreed from observations of the color development with dimethylaminobenzaldehyde that the first bond broken is that which liberates the reducing group of the N-acetylglucosamine. It has been suspected that the decreased turbidity formation as well as the decrease in viscosity of the low viscosity

* Deceased

preparations employed in viscosimetric assays is the result of hydrolysis of glucosidic bonds. However, the absence of exact information on this point has, in general, prevented correlation of information obtained by the 3 different methods. By application of the submicro determination of glucose of Park and Johnson (*J Biol Chem* 181: 149, 1949), it has been possible to show that under the conditions employed for turbidimetric assay of hyaluronidase (MEYER, *K Physiol Rev* 27: 335, 1947), namely, the action of one turbidimetric unit of enzyme on 200 μ g of hyaluronic acid in 1 ml of acetate buffer at pH 6 for 30 minutes, reducing sugar of the order of 2-3 μ g glucose equivalent is liberated, representing 1-2% hydrolysis of the substrate. The reaction responsible for the decreased turbidity formation is thus the same as that measured by the reductimetric method. The suitability of this submicro reducing sugar method for assay of hyaluronidase will be discussed.

Enzymatic conversion of homogentisic acid to fumarylacetoacetate ROBERT G. RAYDIN AND DANA I. CRANDALL (introduced by SAMUEL GURIN) *Dept of Physiological Chemistry, Univ of Pennsylvania, School of Medicine, Philadelphia*

A concentration of 30% alcohol in a water clear centrifugate of homogenized rat liver at 0°C precipitates a protein fraction (I) which converts homogentisic acid into a beta-keto-acid which is very slowly decarboxylated by aniline citrate at 38°C. Another precipitable protein fraction (II) obtained by increasing the alcohol concentration to 50%, discarding the precipitate, and increasing the alcohol to 70%, converts the slowly decarboxylating beta-keto-acid into acetoacetate. The beta-keto-acid was precipitated as a silver salt from a trichloroacetic acid deproteinized incubation mixture of homogentisic acid and protein fraction I. The acid was obtained from the silver salt by acidification and ether extraction and purified by repeated precipitation from ether-petroleum ether. The free acid (M.P. 158°C) titrates as a dicarboxylic acid with an apparent molecular weight of 200. It appears to be a diketone for the following reasons: a) reactions with o-phenylene diamine yields a lavender color similar to that exhibited by beta-diketones (WITTER, SNYDER AND STOTZ *J Biol Chem* 176: 493, 1948); b) two additional titratable groups appear at alkaline pH's, and c) hydrolysis to fumarate and acetoacetate is brought about by a purified protein fraction known to hydrolyze triacetic acid (CONNORS AND STOTZ *J Biol Chem*, 178: 881, 1949). These observations suggest that the acid is fumarylacetoacetate.

Properties of a red cell metabolism regulator

ALLEN F. REID AND ELLSIE B. RYAN (intro-

duced by M. F. MASON) *Southwestern Med School of Univ of Texas, Dallas*

A component of human blood serum has been found to have an inhibiting effect on the rate of phosphate metabolism of human erythrocytes. This component is dialyzable, but not ionically removed by strong anion or cation ion exchange resins. A similar factor is found in the serum of cattle, dogs and mice. None was found in human urine. Physical and chemical properties of this material were similar to those of simple carbohydrates. A much less pronounced but similar effect on red-cell phosphate metabolism was shown by some carbohydrates but not by others, providing a lead to the functioning structural units of the molecule.

Nitrogen trichloride-treated prolamines VII. Further characterization of toxic factor L REINER, F. MISANI,* M. G. CORDASCO* AND T. W. FAIR* *Research Labs, Wallace and Tiernan Products, Inc., Belleville, N. J.*

It has been postulated on the basis of analytical data that the toxic factor is a derivative of methionine (REINER *et al J Am Chem Soc* In press). It differs in composition from methionine only by one additional atom of each hydrogen, nitrogen and oxygen. Furthermore the development of convulsions caused by the toxic factor was found to be suppressed by the administration of large doses of methionine (REINER *et al Arch Biochem* In press). Evidence is now being presented indicating that the methionine skeleton is maintained in this derivative. Hydrolytic degradation with aqueous hydrochloric or sulfuric acid yielded some homocysteic acid identified chromatographically, refluxing with hydriodic acid yielded methyl iodide and a residue which gave a positive nitroprusside test and contained the thiolactone of homocysteine, the latter was converted into homocystine, hydrogenolysis with Raney nickel yielded alpha-amino-n-butyric acid. The toxic derivative was found to be transparent to ultraviolet rays. It seems that only the sulfur atom of methionine is involved in the formation of the toxic derivative.

Metabolism of polyunsaturated fatty acids in chickens RAYMOND REISER (introduced by CARL M. LYMAN) *Texas Agricultural Experiment Station, College Station*

A group of 12 White Leghorn Cockerels were fed a low fat synthetic ration, and 3 similar groups the same basal ration in which 1% bayberry tallow, cottonseed oil or cod liver oil were substituted for 2% sucrose. At the end of 5 weeks the chicks were killed and the polyunsaturated fatty acids of the phospholipids and triglycerides of the carcasses and pooled organs determined by alkaline isomerization. Fatty acids with 5 and 6 double bonds were universally present only in those chicks fed cod liver oil. Five double bond

acids were also found in the organ glycerides and 5 and 6 double bond acids in the organ phospholipids of cottonseed oil fed birds. No evidence of 5 or 6 double bond acids was found in the tissues of the chicks on the fat free or bayberry tallow rations. Arachidonic acid was present in significant amounts in all cases. Linolenic acid was completely absent or present in traces only. Linoleic acid composed about 5% of the triglycerides and 10% of the phospholipids of the tissues of the fat free and bayberry tallow fed chicks, but 10% of the triglycerides and 15% of the phospholipids of the cottonseed oil and cod liver oil groups. It appears that the growing chick cannot convert linoleic acid to 3, 5, or 6 double bond acids but probably does convert it to arachidonic acid. However, when 8-week old chicks were fed conjugated linoleic acid, this acid was not found in the tissues but apparently was converted to a conjugated 3 double bond acid with maximum absorption at 270 m μ .

Purine metabolism in rat liver homogenates

DAN A. RICHERT* AND W. W. WESTERFELD
Dept. of Biochemistry, Syracuse Univ. College of Medicine, Syracuse, N. Y.

The increased oxygen uptake due to the addition of various purines, nucleosides, and nucleotides to rat liver homogenates of varying xanthine oxidase activities was determined. Decreases in liver xanthine oxidase were obtained by feeding a purified 8% casein diet. Normal rat liver homogenates gave a theoretical increase in the oxygen uptake from the addition of guanine, guanosine, xanthosine, adenosine, and adenosine-5-phosphate, due to the oxidation of xanthine and hypoxanthine formed from these substrates by enzymatic hydrolytic reactions. The 3-phosphate derivatives of guanosine and adenosine were hydrolyzed slowly. Adenine gave no oxygen uptake due to the absence of adenase. When the xanthine oxidase activity was reduced to a zero oxygen uptake with xanthine, the homogenate failed to oxidize any of the above substrates. *In vitro* addition of purified milk xanthine oxidase to such a liver preparation restored its normal capacity to oxidize all of the substrates. It was concluded that 1) no unidentified nucleoside or nucleotide oxidative enzymes were present in rat liver, 2) the hydrolytic enzymes involved in nucleotide metabolism were not destroyed by feeding a low protein diet, and 3) inosine was a key intermediate in the formation of uric acid from adenylic acid in rat liver.

γ -Aminobutyric acid in brain EUGENE ROBERTS AND SAM FRANKEL (introduced by C. CARTHERS) *Division of Cancer Research, Washington Univ., St. Louis, Mo.*

Relatively large quantities of an unidentified ninhydrin-reactive material were found in numer-

ous two dimensional paper chromatograms of protein-free extracts of fresh mouse, rabbit, and frog brains. At most, only traces of this material were found in a large number of many other normal and neoplastic tissues and in urine and blood. The eluate from suitably chosen strips of one-dimensional phenol chromatograms of mouse brain extract contained the unknown substance and only traces of valine and an unidentified peptide material. A comparison of the properties of the unknown substance in the eluate with those of known compounds by chromatography in different solvent systems showed it to be identical with γ -aminobutyric acid. This conclusion was independently confirmed by the isotopic derivative method using the I-131- and S-35-labeled p-iodophenyl sulfonyl derivatives (S. Udenfriend). Experiments with brain homogenates showed a formation of γ -aminobutyric acid which appeared to be accelerated when glutamic acid was added. γ -Aminobutyric acid was also formed in homogenates of liver and muscle. Experiments are under way to characterize the precursors of γ -aminobutyric acid and the enzymes involved in its formation.

Role of potassium in cellular metabolism I. Z. ROBERTS (introduced by L. B. FLEXNER), *Carnegie Inst. of Washington, Dept. of Terrestrial Magnetism, Washington, D. C.*

Various methods have been used to investigate the effects of potassium deficiency on cells of *E. coli*. In cells partially depleted of potassium the rates of growth and glucose utilization were reduced. Radioactive tracers gave a more sensitive indication of changes in the metabolic activity of the cells. With glucose as a substrate, cells deficient in potassium showed less incorporation of radioactive sulfate into proteins and less incorporation of radioactive phosphate into phospholipids and nucleic acids. The most marked reduction (factor of 8) was found in the incorporation of phosphate into desoxyribose nucleic acid. With other substrates such as lactate, pyruvate, glutamate, and hexose phosphates, a smaller effect from potassium depletion was found. These observations are in accord with the hypothesis that potassium is involved in one of the early steps in the glucose cycle.

Biological activity of some uridine derivatives MARTIN ROBERTS, T. KAY FUKUHARA AND DONALD W. VISSER (introduced by RICHARD J. WINZLER) *Dept. of Biochemistry and Nutrition, Univ. of Southern California School of Medicine, Los Angeles*

There is evidence that nucleosides are the building stones used by organisms to synthesize the nucleic acid portion of nucleoproteins. It was therefore of interest to synthesize some uridine derivatives and investigate the ability of these

derivatives to replace or antagonize the utilization of naturally occurring nucleosides. Bromouridine (1 D-ribofuranosyl-2,4-dioxy-5-bromopyrimidine) and chlorouridine (1 D-ribofuranosyl-2,4-dioxy-5-chloropyrimidine) were synthesized by bromination and chlorination of natural uridine. Ribosylthymine (1 D-ribofuranosyl-2,4-dioxy-5-methylpyrimidine) was synthesized from thymine and D-ribose. Chlorouridine competitively inhibited the growth of the uracil-requiring mutant of *Neurospora* (1298). The molar ratio of chlorouridine to uridine to produce 50% growth was approximately 4. Ribosylthymine neither replaced nor inhibited uridine under the same conditions. The growth of the wild strain of *Neurospora* was not inhibited by either chlorouridine or ribosylthymine in the concentrations tested. The growth of *Mycobacterium tuberculosis* was not inhibited by bromouridine or chlorouridine but was inhibited by chlorouracil at a concentration of 0.0001 gm in 10 cc medium. Studies are in progress testing these uridine derivatives with thymidine-requiring organisms. The propagation of mouse encephalomyelitis virus, Theiler's GD VII, in cultures of mouse brain is also being investigated.

Influence of adrenal cortex on antibody production in vitro SIDNEY ROBERTS* AND ABRAHAM WHITE, *Dept of Physiological Chemistry, School of Medicine, Univ of California at Los Angeles*

Previous studies have demonstrated that splenic tissue, obtained from rats given a single intravenous injection of sheep erythrocytes 5 days earlier, released large amounts of hemolysin against this antigen on incubation under 95% oxygen, 5% carbon dioxide in serum obtained from non-immunized animals. This release of antibody did not occur when the incubation was carried out under an atmosphere of 100% nitrogen. Similar experiments have been conducted with animals which had been either adrenalectomized 2-4 days earlier, or injected intraperitoneally 2 hours earlier with 2 ml of Wilson's aqueous adrenal cortical extract (ACE). It was found that the amount of antibody released by splenic tissue from adrenalectomized rats was much smaller than that seen with splenic tissue from unoperated animals, and that there was no evidence for new formation of antibody. The level of antibody in the serum of the adrenalectomized animals was slightly lower than that of the control, and definitely lower in extracts of spleen and mesenteric lymph nodes of the adrenalectomized rats. In contrast, splenic tissue from immunized rats injected with ACE produced very large amounts of antibody *in vitro*. In addition, evidence was obtained that the injection of ACE resulted in the release of antibody from spleen

and lymphoid tissue in the intact immunized animals, and in a prolongation of the period of maximal antibody production.

Chemical composition of some bacterial pyrogens.

GERTRUDE RODNEY AND H. B. DEVLIN (introduced by J. J. PIFFNER), *Research Labs., Parke, Davis & Co., Detroit, Mich.*

Pyrogenic material was isolated from strains of *B. prodigiosus*, *E. typhi*, *B. subtilis* and *Ps. aeruginosa* grown on synthetic media. The pyrogens were purified by fractionation with organic solvents after treatment by various procedures to remove protein and nucleic acid. Pyrogen from different sources prepared by the same procedures differed in activity. The most active, from *B. prodigiosus*, reacted in concentrations of 0.01-0.005 µg/kg in rabbits. The pyrogens were analyzed for N and P, and for reducing substances and glucosamine after hydrolysis. Quantitative filter paper partition chromatography was applied to the determination of the sugars present in the hydrolysates, and the composition of the 4 pyrogens was found to differ qualitatively and quantitatively.

The α -glucosaminidase activity of partially purified testicular extract SAUL ROSEMAN* AND ALBERT DORFMAN, *Dept of Pediatrics, Univ of Chicago, Chicago, Ill.*

Partially purified testicular extract was found to hydrolyze N-acetyl-phenyl- α -D-glucosaminide (prepared by way of its tetracetate). This hydrolysis does not parallel hyaluronidase activity as evidenced by the fact that the glycosidase activity was markedly decreased in a more highly purified hyaluronidase preparation. The β -glucosaminidase discovered by Helferich and Ploff (*Z. physiol. Chem.* 221:252, 1933) in emulsin and snail extract (NEUBERGER AND PITT-RIVERS, *Biochem. J.* 33:1580, 1939) had been previously demonstrated in testicular extract (EAST ET AL. *Biochem. J.* 35:872, 1941). This fact has been confirmed thus indicating that crude testicular extract contains both α - and β -glucosaminidases. That the apparent hydrolysis of the α -sugar is not due to β contamination is indicated by the failure of emulsin to act on the α -glucosaminide. These data suggest the presence in testicular extract of a previously undescribed α -glucosaminidase.

Effect of protein starvation on enzyme activity of normal and regenerating rat liver OTTO ROSENTHAL, JAMES C. FAHL*, GORDON M. KARN* AND CHARLES S. ROGERS*, *Harrison Dept of Surgical Research, Univ of Pennsylvania Schools of Medicine, Philadelphia*

The liver enzyme study previously reported (*Federation Proc.* 8:244, 1949) has been extended to include additional enzymes and prolonged

periods of protein-starvation Male 250-gm Wistar rats were used Expressed in terms of mass of protein or of enzyme activity per total liver per 100 gm initial body weight, the following percentages of normal values (obtained with protein-fed rats) were found after 2 and 6 weeks of protein depletion respectively: protein (57%, 50%), arginase (32%, 20%), rhodanese (32%, 29%), nonspecific cholinesterase (43%, 42%), adenosine pyrophosphatase (50%, 46%), alkaline phosphatase (142%, 107%) With the exception of alkaline phosphatase which increased, all enzymes exhibited sharp initial drops which exceeded the protein loss to a varying degree Prolonged protein-starvation produced an additional significant decrease of arginase and a reduction of alkaline phosphatase to normal levels Partial hepatectomy in depleted animals caused a sharp rise in alkaline phosphatase content of the liver remnant The rise which greatly exceeded the protein increase resembled that of arginase previously reported No other enzyme displayed this phenomenon Differential changes of enzymes with gain or loss of liver protein may be explained to a large extent by location differences With arginase and alkaline phosphatase, however, the metabolic state of the animal appears to be an additional factor which controls either quantity or activity of the enzyme

Sulfur balance of rats fed excess DL-methionine plus glycine or DL-alanine JAY S. ROTH*, JAMES B. ALLISON AND LAWRENCE J. MILCH* *Bureau of Biological Research, Rutgers Univ., New Brunswick, N. J.*

Four groups of mature, male Sherman strain rats were fed a basic 12% casein diet and in addition to this, *Group II* was fed 4.8% DL-methionine, *Group III*, 4.8% DL-methionine plus 4.8% glycine, and *Group IV*, 4.8% DL-methionine plus 5% DL-alanine All the groups were fed the same weight of diet consumed by *Group II* over 20-day period Nitrogen and sulfur balances were determined on the 4 groups and in addition, liver and kidney weights, liver fats and plasma pseudocholinesterase Urinary sulfur partitions were performed also and it was found that in *Group I*, two-thirds of the urinary sulfur was excreted as sulfate and one-third as organic sulfur This proportion was maintained in *Groups II* and *IV*, but in *Group III*, excess glycine favored the excretion of sulfur in the organic form The animals in *Group III* were in sulfur balance while those in *Groups II* and *IV* maintained a positive sulfur balance equivalent to 10% of the ingested sulfur Excess glycine counteracted in part the kidney hypertrophy and weight loss observed when excess methionine was fed but an equivalent quantity DL-alanine had no significant effect in this way

showing that the action of glycine was quite specific High liver fat values were observed in rats fed excess methionine plus alanine

Enzymatic formation of citric acid studied with C¹⁴-labeled oxalacetate HARRY RUDNEY*, VICTOR LORBER, M. F. UTTER AND MARGARET COOK* *Dept. of Biochemistry, Western Reserve Univ. School of Medicine, Cleveland, Ohio*

The concept that citrate may behave as an asymmetrical molecule in enzymatic reactions, proposed by Ogston (*Nature* 162:963, 1948) and supported by the work of Potter and Heidelberger (*Nature* 164:180, 1949), removes prior objections to the inclusion of citrate in the main path of the Krebs cycle In addition, Stern and Ochoa (*J. Biol. Chem.* 179:491, 1949) have demonstrated citrate formation from oxalacetate and acetate in an enzyme preparation containing negligible aconitase activity, indicating that citrate may be the primary reaction product This implies condensation of the methyl carbon of acetate on the carbonyl group of oxalacetate This reaction was studied in an enzyme preparation similar to that of Stern and Ochoa using non-isotopic acetate and C¹⁴- β -carboxyl labeled oxalacetate, prepared enzymatically and isolated by partition chromatography The resulting C¹⁴-citrate (plus carrier) was isolated by partition chromatography and the quinidine derivative prepared Degradation to yield the non-carboxyl carbons, the tertiary carboxyl, and primary carboxyls, as three separate fractions, and enzymatic conversion to α -ketoglutarate followed by α -decarboxylation revealed significant activity only in the primary carboxyl corresponding to the α -carboxyl of α -ketoglutarate These results are in accord with the reaction mechanism postulated for citrate formation from acetate and oxalacetate, and confirm the observations of Potter and Heidelberger offered in support of Ogston's proposal Oxalacetate, recovered after incubation of C¹⁴-citrate with the citrate-forming enzyme in the presence of non-isotopic acetate and oxalacetate, contained no activity, suggesting though not establishing the irreversibility of the condensation reaction

Inheritance of rate of protein synthesis in the liver of inbred strains of rats ROBERT RUTMAN (introduced by HAROLD TARVER) *Univ. of California, Berkeley*

Two inbred strains of rats, differing in body weight, were compared as to *in vitro* incorporation of S³⁵ labeled DL-methionine into the protein of liver slices The heavier F strain (Wistar Albino) showed 50-57% greater uptake than did the lighter J strain (Fisher #344), for the 3-4 generations tested Mature FJ and JF and young FJ hybrids showed essentially the same *in vitro* activity as the F parent Young JF hybrids were not signifi-

cantly different from the J parent. Average activities for backcrosses showed no significant differences from the higher inbred strain. However, the distribution of individual values showed that 45% of the offspring of J males and hybrid females resembled the J strain, whereas 95% of the comparable F offspring equalled or exceeded the F strain. Foster nursing of J males on inbred F mothers raised the liver activity to the level of the foster parent. Fostering of F males had no effect. Thus, the characteristic liver activities are determined by both the individual and the maternal genotypes. Backcross segregation suggests that a single genetic factor contributes a major portion of the strain difference. The superior potency of this factor in the F strain is shown by the equivalence of the hybrids. Maternal influence is shown in the depressed activity of young hybrid liver tissue and is confirmed by the foster nursing studies.

Acetone metabolism in the intact rat WARWICK

SAKAMI *Dept of Biochemistry, Western Reserve Univ School of Medicine, Cleveland, Ohio*

Borek and Rittenberg (*J Biol Chem* 179 843, 1949) have indicated that acetone is metabolized at least in part via acetate in surviving rat liver. We have found that it also contributes to the pool of 'formate' or formate derivative for which the β -carbon of serine is used as an indicator. Acetone is also converted to the methyl groups of choline and methionine. When C^{14} -methyl-labeled acetone was administered to rats, the β -carbon of the isolated serine and the methyl carbons of the choline and methionine contained appreciable activity. The formation of the β -carbon of serine from formate did not occur via acetate. When C^{14} -methyl-labeled acetate replaced the acetone in a parallel experiment, the β -carbon of serine contained negligible activity. Comparison of the incorporation of C^{14} into the β -carbon of serine from methyl labeled acetone and formate (Sakami *J Biol Chem* 176 995, 1948) indicate that formate formation is a major mechanism of acetone metabolism under these conditions. This suggests that the principal pathway of acetone utilization involves cleavage of its carbon chain into acetate and formate or substances derived from these compounds. The finding of C^{14} in the methyl groups of choline and methionine afforded the possibility that the synthesis of labile methyl groups occurred via formate.

Studies on the biosynthesis of chlorophyll KURT

SALOMON, KURT I. ALTMAN AND ROCCO DELLA ROSA (introduced by W. R. BLOOR) *Dept of Radiation Biology, Univ of Rochester, Rochester, N. Y.*

The utilization of the alpha-carbon atoms of glycine and acetic acid in the biosynthesis of

chlorophyll by *Chlorella vulgaris* has been investigated. *Chlorella* cells were grown in a synthetic sterile medium containing mineral supplements and 1% glucose. To this medium were also added either sodium acetate or glycine labeled with C^{14} in their respective alpha-carbon atoms and having a C^{14} -activity of 2.57×10^3 and 2.55×10^3 disintegrations/min/ μ M carbon respectively. The final concentration of glycine and acetate in the medium was 0.01M. The cells were grown for one week under stationary conditions in fluorescent light at pH 5.8, and were then harvested by centrifugation. The harvested cells were washed with water and then with dilute solutions of either inert glycine or inert acetate. The *Chlorella* cells were then extracted exhaustively with dioxane and the chlorophyll thus prepared was precipitated with a concentrated aqueous NaCl solution. The chlorophyll preparation was purified by several reprecipitations with NaCl and converted to methylpheophorbide, which was recrystallized several times from chloroform-ligroin. The contribution of the alpha-carbon atom of acetate to methylpheophorbide was 3.5 times greater than that of the methylene-carbon atom of glycine. In the case of *Chlorella* grown in the presence of acetate, the isotope dilution of methylpheophorbide isolated was 20 as compared with 60 in the case of *Chlorella* grown in the presence of glycine. The data indicate that *Chlorella vulgaris* is able to utilize directly the alpha-carbon atoms of glycine and acetate for the biosynthesis of chlorophyll.

Physiopathology of intermediary carotene metabolism in animal organism STELIOS C.

SAMARAS, WILLIAM REALS AND DANIEL HINGERTY (introduced by VICTOR E. LEVINE) *Depts of Biological Chemistry and Nutrition, and Pathology, Creighton Univ School of Medicine, Omaha, Nebr.*

Forty male white rats, 4 weeks old and divided into groups, were put on a vitamin A-deficient diet. When the classical symptoms appeared, the animals were given orally 400 U.S.P. units of carotene in oil. Control animals were able to build up great reserves of vitamin A without accumulation of carotene (carotene liver 2.3 μ g/gm, intestine (small) 3.5 μ g/gm, lung 3.1 μ g/gm, vitamin A liver 85.1 μ g/gm, intestine 1.5 μ g/gm, lung 1.8 μ g/gm). Rats, 4 weeks deficient, with liver vitamin A less than 1 μ g/gm, without ocular symptoms and with considerable weight loss, showed immediate gains in weight after carotene administration. Killed one week later they had carotene liver 3.8 μ g/gm, intestine 2.1 μ g/gm, lung 2.0 μ g/gm, vitamin A liver 9.1 μ g/gm, intestine 1.2 μ g/gm, lung 0.9 μ g/gm. Rats with more advanced deficiencies also showed striking amelioration, but lasting only 2-5 weeks. No

measurable quantity of vitamin A was found in their organs. Very severely deficient rats with marked hemorrhagic conjunctivitis were unable to convert given carotene, dying despite the presence of appreciable carotene (carotene: liver 8.1 $\mu\text{g/gm}$, intestine 12.6 $\mu\text{g/gm}$, lung 7.3 $\mu\text{g/gm}$). Histological examinations showed that deficient animals first develop reversible changes. In advanced stages the alterations are irreversible, impairing carotene absorption and conversion. Especially in gastrointestinal tracts of animals with advanced symptoms we found a marked desquamation of the columnar epithelium. This was especially prominent in animals unable to use the administered carotene. Evidently in vitamin A deficiency vitamin A, not carotene, should be administered.

A simple densimetric determination of heavy water LEO A. SAPIRSTEIN (introduced by WALTER MARX) *Dept. of Physiology, Univ. of Southern California Med. School, Los Angeles*

Density determinations can be performed on deuterium oxide-water mixtures with an accuracy of 3 parts in a million by the present method, which requires only standard laboratory equipment and a Beckman differential thermometer. A small hollow glass bead is prepared and its specific gravity is adjusted by trial and error until it just sinks in redistilled water at 20–25°C. The temperature at which this bead just begins to float is determined to 0.1°C for standard D_2O - H_2O mixtures ranging from 0–2%. With pyrex beads the end-point for 2% D_2O is 7°C higher than for distilled water and the plot of temperature vs. D_2O concentration is linear. By substituting a redistilled sample of the unknown D_2O - H_2O mixture, and determining the end-point temperature, the D_2O concentration may be read directly from the calibration curve. The method differentiates D_2O concentrations of 3×10^{-5} with no difficulty. Samples containing approximately 1% D_2O in water have been determined with an accuracy of 0.3% by this method.

Concentration of the factor required for the growth of *Leuconostoc citrovorum* 8081 H. E. SAUBERLICH (introduced by W. D. SALMON) *Lab. of Animal Nutrition, Alabama Polytechnic Inst., Auburn*

Further studies were made on the concentration of the factor from Wilson's liver 'L'. This was dissolved in water, adjusted to pH 3.0 with sulfuric acid and treated repeatedly with charcoal (Norite A) at room temperature. The factor was eluted from the charcoal with ethyl alcohol-water-ammonium hydroxide solution at 65°C. The eluate was evaporated to dryness and the residue taken up in water. The solution was adjusted to pH 3.0 with sulfuric acid and the precipitate filtered off. The

filtrate was extracted repeatedly with n-butyl alcohol at a pH of 3.0. The butyl alcohol fractions were then extracted with water at pH 8.5. The water extracts were adjusted to pH 7.0 and passed over amberlite columns to remove anions and cations. The filtrate was evaporated partially and then extracted at a pH of 3.0 with butyl alcohol. The butyl alcohol extract was further purified by partition chromatography. This was accomplished by placing the solution on potato starch columns and developing with butyl alcohol saturated with water and made acidic with acetic acid. Various bands and fractions were collected and analyzed microbiologically for activity. Active fractions were further purified by partition chromatography. In this manner concentrates of the unknown factor were obtained which were exceedingly active and of very low solids content. Details of the procedure employed and the preparations obtained will be presented.

Effect of adrenal mince and cell-free filtrate on desoxycorticosterone KENNETH SAVARD*, LENA A. LEWIS* AND ARDA ALDEN GREEN *Research Division, Cleveland Clinic Foundation, Cleveland, Ohio*

Desoxycorticosterone has been incubated with minced or filtered extracts of beef adrenal tissue. The neutral steroid fraction extracted from these incubation mixtures exhibits glycogenic activity in fasting adrenalectomized mice (Venning test). This activity is substantially greater than that of the controls incubated without added desoxycorticosterone. Studies on possible coenzymes, on different substrates, and on the chemical characteristics of the products will be reported.

Ketoglutaric acid carboxylase in higher plants

OTTO SCHALES, SELMA S. SCHALES* AND GAYLE M. SCHWARZENBACH* *Chemical Research Lab., Alton Ochsner Medical Foundation, and Dept. of Biochemistry, Tulane Univ. School of Medicine, New Orleans, La.*

Extracts from a variety of higher plants were found to decarboxylate pyruvic acid (PA) and α -ketoglutaric acid (KGA). The addition of phenol (2 mg/ml) to the incubation mixtures completely inhibited the decarboxylation of PA, but interfered less strikingly with the decarboxylation of KGA, suggesting that the two keto acids were attacked by different enzymes. Extracts from different plants varied widely in their activity against PA and KGA. Cucumber extract, for example, decarboxylated PA, but had no significant effect on KGA. Various types of potatoes yielded extracts with considerably higher activity against KGA than against PA. Squash, corn and cantaloupe were found to be particularly rich in KGA carboxylase. The new enzyme (from squash) showed optimal activity at pH 6.0–6.1. It lost 95%

of its activity after 17 hours dialysis against 30-40 volumes of distilled water, while PA carboxylase was only slightly inactivated by this treatment. Both carboxylases were reactivated on addition of concentrated dialysate to the dialyzed material. PA carboxylase but not KGA carboxylase was also activated on addition of diphosphothiamin (cocarboxylase) plus Mg or Mn ions to extracts which had been dialyzed for several days. Yeast extract (Difco) activated dialyzed KGA carboxylase but did not activate dialyzed PA carboxylase. The easily removable prosthetic group of KGA carboxylase is not identical with diphosphothiamin.

Intracellular localization of uricase activity

ARNOLD H. SCHEIN, ESTELLE PODBER AND ALEX B. NOVIKOFF (introduced by H. B. PIERCE)
Depts. of Biochemistry and Pathology, Univ. of Vermont, College of Medicine, Burlington

Nuclei, mitochondria, sub-microscopic particles and 'supernatant fluid' were separated from rat liver homogenate by differential centrifugation. The uricase activity of each fraction, of the original homogenate and of a mixture prepared by combining the separated fractions in the proportions found in the homogenate were measured. Three dilutions of tissue were incubated with a known amount of uric acid in borate buffer pH 9.3, at 45°C in a Dubnoff Metabolic Shaking Apparatus. Under the conditions employed, uricase activity (μg uric acid destroyed/30 min) was in each case proportional to the quantity of tissue used. Seventy to 80% of the uricase activity was found in the mitochondrial fraction, 10 to 15% in the nuclear fraction. Little or no activity could be demonstrated for the sub-microscopic particles and the supernatant fluid. The uricase activity of the mixture closely approximated that of the original homogenate, indicating the absence of interaction among the materials of the 4 fractions. As a check on the effective separation of the fractions, nucleic acids (DNA, PNA) and succinoxidase determinations were made. The fractions were also examined microscopically (phase contrast). The mitochondrial contamination (as free particles or in unbroken cells) may account for the uricase activity of the nuclear fraction. The mitochondrial fraction was completely free of nuclei.

Nature of rabbit liver glycogen

MAX SCHLAMOWITZ (introduced by DAVID M. GREENBERG)
Division of Biochemistry, Univ. of California Med. School, Berkeley

Studies have been carried out on the influence which type of carbohydrate and the mode of its administration has in determining the structure of glycogen deposited in rabbit livers. Measurements of degree of branching and iodine adsorbing and light scattering properties have been used to es-

tablish differences in the structures of the several glycogens isolated. The end-group assay as determined by periodate oxidation was found to correspond to an average branch-length of 19 to 25 glucose residues, depending on the type carbohydrate administered and the mode of its administration. Under no condition thus far tested has it been possible to produce the more highly branched 12 unit glycogen, generally considered to be the 'normal' glycogen. Glycogens with low-degrees of branching such as those obtained in the present investigations, have in the past been considered 'abnormal'.

Action of ribonuclease and its bearing on structure of yeast ribonucleic acid

GERHARD SCHMIDT, NEPOMUK ZÖLLNER*, LISA HECHT*, RICARDO CUBILES*, MARIA WARGON* AND S. J. THANNHAUSER
Tufts College Med. School, Boston, Mass.

Prostate phosphatase releases from yeast RNA 7 to 8% of its total P as inorganic phosphate without formation of nucleosides. After precipitation of the total P with uranium acetate the supernatants contained negligible amounts of nitrogen, phosphatase action did not lead to an increased consumption of periodate. After digestion with ribonuclease, approximately one half of the total phosphorus of RNA was hydrolysed by phosphatase. The pyrimidine nucleotide groups were practically completely dephosphorylated, the purine nucleotide groups were practically completely preserved as polynucleotides. The uranium supernatant contained no purines. The periodate test showed that 70 to 80% of the pyrimidine groups were liberated as free nucleosides, the rest remained in linkage with the purine polynucleotides. Yeast ribonucleic acid consists of long chains of purine nucleotides linked to long chains of pyrimidine nucleotides. Titration experiments showed that a large part of the alkali uptake of yeast RNA between pH 5 and pH 8.5 originates from groups other than secondary phosphoryl groups. Crystallized ribonuclease does not hydrolyse pancreas RNA. Pancreas contains a second ribonuclease (B) which hydrolyses yeast and pancreas RNA. Its action differs from that of Kunitz's ribonuclease because ribonuclease B hydrolyses the cross-linkages between the purine nucleotide groups.

Isolation of adrenocortical compounds from normal male urine

JOHN J. SCHNEIDER (introduced by F. L. MUNRO)
Dept. Exper. Med., Jefferson Med. College, Philadelphia, Pa.

Large volumes of pooled, normal male urine were extracted with chloroform both before and after adjustment to pH 1. Further fractionation included recovery of the ketonic fractions, their partitioning between benzene and water and chro-

matography of the acetylated residues. Of the crystalline compounds recovered, one has been shown to be 17-hydroxy 11-dehydrocorticosterone which was isolated largely as the free compound in an over-all yield of 55.3 γ /l and another, the corresponding tetrahydro derivative, 3(α),21-di-acetoxy-17(α)-hydroxypregnanetriol-11,20-dione. Three other crystalline compounds and one non-crystalline substance have been partially characterized. Two of these are regarded as reduction products and the remaining two as possibly physiologically active compounds. These results will be discussed in relation to other relevant data.

Effect of ultraviolet irradiation on certain amino acids KLAUS SCHOCKEN (introduced by H. JENSEN) *Med. Dept. Field Research Lab. Fort Knox, Ky.*

The degree of decomposition of the following amino acids: phenylalanine, tyrosine, dihydroxyphenylalanine, histidine and tryptophane by ultraviolet irradiation has been studied quantitatively. The buffered amino acid solutions were irradiated with the unfiltered light of a Hanovia quartz mercury lamp at 30 cm. distance in test tubes of about 1 in. diameter, which were placed in a water bath. The degree of conversion of benzoic acid to hydroxybenzoic acid, of phenylalanine to tyrosine, and of tyrosine to dopa by ultraviolet irradiation has been determined. The significance of these findings will be discussed. Histidine has been found to be very sensitive to ultraviolet irradiation and was therefore used to study the effect of certain compounds which were expected to inhibit the decomposition effect of ultraviolet irradiation. Cysteine, cystine, homocystine and methionine were found to exert a pronounced inhibiting response. In addition, experiments on the influence of compounds which were expected to accelerate the irradiation effect have been carried out.

Precursors of purines MARTIN P. SCHULMAN,* JOHN M. BUCHANAN AND CHARLES S. MILLER* *Dept. Physiological Chemistry, School of Medicine, Univ. of Pennsylvania, Philadelphia*

There is appreciable disappearance of C^{14} -labeled 4-amino-5-imidazole carboxamide (synthesized by method of Miller and Gurin) when incubated with pigeon liver homogenates. When carrier hypoxanthine was added at the experiment's conclusion, radioactivity was found in the isolated hypoxanthine in quantities indicating that most of the disappearing carboxamide was converted to hypoxanthine. The hypoxanthine was precipitated by ammoniacal silver nitrate and purified by 3 passages through a starch column (butanol-water). Since rigorous purine characterization is necessary, further attempts are being made to separate the radioactivity from the purified hypoxanthine. Nevertheless hypoxanthine

contaminated with C^{14} -carboxamide in control experiments may be freed of radioactivity by the above procedure. Furthermore, radioactive uric acid was excreted by a pigeon administered C^{14} -carboxamide. Inappreciable isotope concentration was present in the respiratory CO_2 . Further experiments have shown that $NH_2CH_2C^{14}OOH$ and $HC^{14}OOH$ participate in hypoxanthine synthesis *in vitro* at a rate comparable to C^{14} -carboxamide utilization. A previous report (Sonne, Buchanan, Delluva) that acetate is involved in uric acid synthesis has not been substantiated. $CH_3C^{14}OOH$, synthesized from $C^{14}O_2$, failed to be incorporated into the purine ureide groups when administered to a pigeon or added to pigeon liver homogenates. When acetate was synthesized from isotopic $NaCN$ and $(CH_3)_2SO_4$, formic acid was a significant by-product and was undoubtedly responsible for the appearance of isotope in the ureide carbons of uric acid in the earlier experiments with C^{12} -acetate.

Nature of the hepatic protein lost during a 2-day fast JULIUS SCHULTZ* AND HARRY M. VARS *Harrison Dept. of Surgical Research, School of Medicine, Univ. of Pennsylvania, Philadelphia*

The total heat-coagulable protein of the livers of fed, 24-hour and 48-hour fasted rats were analysed for nitrogen, ash, glycogen, total-S, cystine-S, phosphorus and purine-N. In terms of the liver of a 'standard' 200-gm. rat, it was found that during the first 24 hours of fasting there was a loss of 268 mg. protein, 30 mg. nucleic acid, 3.6 mg. total-S and 0.4 mg. cystine-S. During the second 24 hours of fasting there was lost 183 mg., 5 mg., 2.2 mg., and 1.2 mg. respectively of the above constituents. This indicates that the proteins lost from the liver during the first day of fast contains little cystine-S while that lost during the second day contains much more. The nucleic acids lost during the first day were greater than that lost later. These data suggest that the composition of the 'labile' proteins of the liver may differ from that of the more metabolically 'stable' proteins.

Preparation of a soluble, purified succinic dehydrogenase CHARLES R. SCOTT (introduced by ELMER STOTZ) *Dept. Biochemistry, Univ. of Rochester School of Medicine and Dentistry, Rochester, N. Y.*

Succinic dehydrogenase, defined by its ability to catalyze the reduction of an electromotively active dye by succinate, has been prepared from pig heart muscle extract in a form which is not sedimented by centrifugation at 20,000 g . The rate of reduction of sodium 2,6-dichlorobenzenonendo-3-chlorophenol, measured aerobically and within a two-minute reaction period, was used for enzyme assay. The typical buffer extract of heart muscle is fractionated with ammonium sulfate in the presence of cholate, the appropriate fraction

subjected to partial heat denaturation, followed by further ammonium sulfate fractionation. The final clear, yellow solution contains the enzyme with some 20-fold purification over the heart muscle extract. It contains less than 0.04% cholate and some ammonium sulfate. The enzyme is precipitated by dialysis against water or buffer, but the activity is retained in a clear solution when dialyzed against strong ammonium sulfate solutions. The final preparation is free of cytochrome oxidase and cytochrome *c*, but shows a weak band at 560 m μ after dithionite reduction. Parallel studies of hemin content and enzyme activity at various stages of purification do not indicate any necessity of a hemin for succinic dehydrogenase activity. The apparently low flavin content has not yet justified a similar study of flavin and enzyme activity. The preparation no longer catalyzes the reduction of cytochrome *c* by succinate unless another heart muscle fraction is added.

Amino acids in two tuberculin protein fractions

FLORENCE B. SEIBERT AND PAUL W. KENT*

Henry Phipps Inst. Univ. of Pennsylvania, Philadelphia, and Dept. of Chemistry, Univ. of Birmingham, England

Protein fractions with different physico-chemical and biological properties have been isolated previously from unheated culture filtrates of a number of different strains of tubercle bacilli grown upon a non-protein synthetic medium. Two of these fractions with the most different properties, designated as A and C fractions, were chosen for a preliminary study of their amino acid composition. By the paper chromatographic method at least 10 amino acids and also one or two unidentified spots, possibly di- or tri-peptides, were identified in both A and C fractions. Quantitative chemical analyses of each fraction showed more tryptophan by the Bates' method, and more phenolic groups, by the Folin reagent, in unhydrolyzed samples of the A than of the C fraction. On hydrolysis, however, still more phenolic groups appeared in the A fractions, but not in the C fractions, indicating that some of the phenolic groups in the A fractions are inaccessible until released by hydrolysis. In analogy with work by many investigators on other physiologically active proteins, such as pepsin, papain, insulin, viruses, etc., it is interesting that this tuberculo-protein A fraction, which contains some of these apparently combined phenolic groups, is also the most potent fraction isolated, in regard to tuberculin activity and antigenicity. It is also the least chromogenic one, as well as the least stable in regard to solubility properties. It is, furthermore, from the A fraction that it is most difficult to separate carbohydrate, and while some carbohydrate can be easily removed, it is not yet certain how much may actually be strongly combined with the protein.

Effect of carbon dioxide on rate of denitrogenation in human subjects JULIUS SENDROY, JR. AND RODOLFO MARGARIA* *Naval Med. Research Inst., Bethesda, Md.*

Following exposure to pressure at 2 atmospheres (absolute) for 4 hours, the elimination of N₂ from the body has been measured in human subjects over periods of from 10^{a-b} minutes to 50-120 minutes of inhalation of an N₂-free gas mixture. The N₂ elimination over such periods following decompression, may be described as the resultant of simultaneous processes, the rate of which may be expressed as a function of time, by the sum of exponential terms of the type $Y = 10^{a-bt}$, of which 2 are given special consideration. On breathing a 3% CO₂ - O₂ mixture, the rate is not appreciably altered. A 5% CO₂ - O₂ mixture causes an increase of 70% in the velocity constant of the fast rate component, while it may slightly decrease the speed of the slow process. An increase of ventilation per se has no effect on the N₂ exchange over the time interval studied as is shown when the subject inhales a low CO₂ mixture (3%), or when the ventilation is increased by the introduction of a respiratory dead space. The effect of the 5% CO₂ mixture is attributed to an increased blood flow through some areas (watery tissues, muscles etc.) and to a decrease in others (fatty tissues). On inhalation of such a mixture, during the first 30 minutes of denitrogenation, 20% more N₂ is given off than when pure O₂ is breathed. It is suggested that CO₂ may possibly be effective in diminishing the incidence of decompression sickness in divers.

Blood volume of the rat measured by the tagged-erythrocyte dilution method L. M. SHARPE,* G. G. CULBRETH* AND J. R. KLEIN *Biology Dept. Brookhaven Natl. Lab., Upton, N. Y.*

Male rats of the Sprague-Dawley strain, weighing from 260 to 340 gm., were injected, via the superficial epigastric vein, with 0.5 ml. of fresh rat blood the cells of which had been tagged with Fe⁵⁹. After 1-2 hours the animals were again anesthetized and bled maximally from the aorta. From the radioactivities of donor and recipients blood, the average blood cell volume and its standard deviation were calculated to be 2.35 ± 0.18 ml./100 gm. body weight. The corresponding average blood volume and its deviation, estimated from the cell volumes and hematocrit, were 4.83 ± 0.31 ml./100 gm. The blood volume found is markedly less than most derived from plasma-labeling, but agrees well with that found in another strain of rat (BERLIN ET AL. *Proc. Soc. Exper. Biol. & Med.* 71, 1949) by means of cell-labeling.

C¹⁴-lactic acid as acetylating agent in intact rat and in rat liver and kidney slices WALTON W. SHREEVE (introduced by JOHN A. MUNTZ)

Dept of Biochemistry, School of Medicine, Western Reserve Univ, Cleveland, Ohio

Conversion of C^{14} α -labeled lactate to acetyl groups was studied in normal rats and in rat liver and kidney slices. Phenylaminobutyric acid was fed, or incubated *in vitro*, together with the labeled compound. The resulting acetylated foreign amine was isolated from the urine or incubation medium, the acetyl group split off, and the isotope content of its individual carbons determined. Entrance of α -labeled lactate (via pyruvate) into reactions of the Krebs cycle should generate pyruvate labeled to a considerable extent in the β as well as the α carbon. This expectation is based on the finding that after feeding α -labeled lactate, carbons 1 and 6 of the glucose derived from rat liver glycogen contain $\frac{1}{2}$ — $\frac{1}{3}$ as much isotope as found in carbons 2 and 5 (LORBER ET AL *Am J Physiol* 155 452, 1948). Of the isotope present in the acetyl groups isolated from the whole animal and the kidney slices, on the other hand, only 10% occurred in the methyl carbon. Acetylation by liver slices was negligible compared with kidney. From these findings it may be inferred that kidney is a main site of occurrence of the acetylation reaction under study, and that in this organ the major fraction of the isotope entering the acetyl groups from lactate does so without prior passage through the Krebs cycle, in contrast to the pathway from lactate to liver glycogen.

Reversible inhibition of the clotting of fibrinogen

SIDNEY SHULMAN* AND JOHN D. FERRY *Dept of Chemistry, Univ of Wisconsin, Madison*

The conversion of bovine fibrinogen to fibrin by thrombin can be markedly retarded by a number of reagents at moderate concentrations (2–5%). The normal clotting time (about 12 min at pH 6.3, ionic strength 0.45, 1 unit/ml thrombin) is prolonged to well over 24 hours by a characteristic minimum concentration of each reagent. These inhibitors can be classified in 3 groups: 1) neutral molecules, 2) anions and 3) cations. Their characteristic functional groups are hydroxyl, amino, sulfonic acid and sulfhydryl, but the whole molecular arrangement seems to be significant, since many of the inhibitors are closely related structurally, while certain other compounds, quite similar in structure, fail to produce inhibition. The inhibition can be shown to be reversible and not due to any permanent protein damage. Normal clotting results from dialysis of inhibited mixtures, furthermore, dialysis of a mixture of one of the proteins with reagent yields a solution that gives the normal clotting behavior with the other protein. Addition of the reagent after the mixing of fibrinogen and thrombin, at any time up to the moment of clotting, also results in reversible inhibition.

Metabolism of N-valeric acid in the intact rat, studied with γ - C^{14} , carboxyl- C^{13} labeled valerate IRWIN SIEGEL (introduced by JOHN A. MUNTZ) *Dept of Biochemistry, School of Medicine, Western Reserve Univ, Cleveland, Ohio*

Solutions of $CH_3C^{14}H_2CH_2CH_2C^{13}OONa$ and glucose were administered to fasted rats by stomach tube. The respiratory CO_2 was collected hourly for 3 hours, at the end of which time the liver glycogen was isolated, hydrolyzed to glucose, and the position of C^{14} and C^{13} in the glucose molecule determined. C^{13} appeared only in carbons 3 and 4, at too high a concentration to be explained by CO_2 fixation alone, while C^{14} was found predominantly and equally in carbons 1, 2, 5 and 6. The respiratory CO_2 contained about twice as much C^{13} as C^{14} , expressed as percentage of isotope administered. These results indicate clearly that the carboxyl and γ carbons of valerate follow different metabolic pathways. Of the various possible mechanisms, the only plausible one which is consistent with the data involves β oxidation to yield $CH_3C^{13}OOH$ and $CH_3C^{14}H_2COOH$. The distribution of isotope in liver glycogen following the feeding of carboxyl-labeled acetate and α -labeled propionate (LIFSON ET AL *J Biol Chem* 176 1263, 1948, LORBER ET AL *Federation Proc* 8 99, 1949) coincides with the patterns observed in the present study. The report by Atchley (*J Biol Chem* 176 123, 1948), who identified propionate and acetate in a kidney enzyme preparation incubated with valerate, is in harmony with the present results obtained in the intact animal.

Biological formation of formate and formaldehyde from methyl compounds in liver slices PHILIP SIEKEVITZ* AND DAVID M. GREENBERG *Division of Biochemistry, Univ of California Med School, San Francisco*

The formation of formate and formaldehyde was studied with C^{14} -labeled compounds. The radioactive compounds were isolated by the carrier method. The formate was determined by steam distilling the compound and oxidizing it to CO_2 with mercuric oxide, the formaldehyde was isolated by steam distillation into dimedon solution and recrystallization of the resulting methylenebis methone to constant specific activity. The methyl group of methionine and choline have been found to give rise to formate and to formaldehyde and can serve as a source of the β -carbon of serine. These reactions are inhibited by ethionine. Intraperitoneal injection of ethionine inhibits the *in vitro* production of formate from glycine but not the synthesis of serine from glycine. The α -carbon of glycine and the β -carbon of serine have been found to form both formaldehyde and formate. Formate production from the above 4 compounds,

except for choline, was greater in air than in nitrogen. With the exception of serine, formaldehyde production was higher in air than in nitrogen. The amount of labeled formaldehyde obtained was small compared to the formate formed.

Synthesis of some phosphate fractions in the threonine-deficient rat S A SINGAL, V P SYDENSTRICKER,* JULIA M LITTLEJOHN,* H T HAYES* AND S J HAZAN* *Univ of Georgia School of Medicine, Augusta*

In the attempt to determine the specific biochemical defect responsible for the fatty livers in rats resulting from threonine deficiency (SINGAL, SYDENSTRICKER AND LITTLEJOHN *Federation Proc* 8 251, 1949) radiophosphorus has been employed in the study of the turnover of inorganic, acid soluble, phospholipid and nucleoprotein phosphorus fractions in the liver, kidney and small intestine of the deficient and normal rat. The relative specific activity of the phospholipid and nucleoprotein fractions of the kidney and small intestine is not significantly different in the deficient and normal animal. The administration of a single dose of 0.2 mM DL-threonine does not alter the activities. In the liver the phospholipid activity is similarly unaffected by either threonine deficiency or by supplementary threonine. In the nucleoprotein fraction, however, the relative specific activity is significantly depressed 30% in the deficient rat. The administration of a single dose of threonine increases the uptake 26%. In the rat receiving an adequate quantity of the amino acid in the diet, supplementary threonine is without effect on the uptake of radiophosphorus.

Isolation of L-amino acid oxidase from moccasin venom THOMAS P SINGER, EDNA B KEARNEY* AND EVELYN A HEISLER* *Dept of Biochemistry, Western Reserve Univ School of Medicine, Cleveland, Ohio*

The preparation of the L-amino acid oxidase of moccasin venom involves the use of $\text{Ca}_3(\text{PO}_4)_2$ gels under rigorously controlled temperature, pH, and ionic strength. Impurities are removed by heating to 73° C for 5 minutes in the presence of L-leucine, followed by adsorption of inert proteins on $\text{Ca}_3(\text{PO}_4)_2$ gel at pH 6. The enzyme is next adsorbed at its isoelectric point on $\text{Ca}_3(\text{PO}_4)_2$ gel and the latter is washed with acetate buffer. The enzyme is eluted with 0.65 saturated $(\text{NH}_4)_2\text{SO}_4$ at its isoelectric point and precipitated by further addition of $(\text{NH}_4)_2\text{SO}_4$. In this manner, the oxidase is obtained in nearly pure form in good yield in a few hours working time. The purity of the enzyme has been studied by electrophoresis, diffusion, solubility measurements and in the ultracentrifuge. The absorption spectrum is characteristic of flavoenzymes, with maxima at 273, 389, and 465 m μ . These peaks are bleached in the presence

of L-leucine, even under aerobic conditions. The prosthetic group has been separated and identified as FAD by its absorption spectrum, by its fluorescence before and after hydrolysis with nucleotide pyrophosphatase or CCl_3COOH , by the quantitative measurement of the adenosine-5-phosphate content following enzymatic hydrolysis, and by the demonstration of the presence of adenine by paper chromatography. The prosthetic group quantitatively replaces FAD in the D-amino acid oxidase test, and it activates cytochrome reductase, a flavin mononucleotide enzyme, only after hydrolysis by nucleotide pyrophosphatase.

An inter-relationship between arginine and proline in metabolism of *Leuconostoc mesenteroides* P-60 R J SIRNY,* L T CHENG* AND C A ELVEHJEM *Dept of Biochemistry, Univ of Wisconsin College of Agriculture, Madison*

Investigations into possible causes of the marked lag observed in the standard curve response to proline under the routine conditions of microbiological analysis with the Henderson-Snell uniform medium (*J Biol Chem* 172 15, 1948) have revealed an unusually high requirement for arginine when proline is limiting and vice versa, in *Leuconostoc mesenteroides* P-60. The unmodified medium normally contains 400 μg L-arginine HCl and 200 μg L-proline in 2 ml, though 20 μg L-arginine and 10 μg L-proline are sufficient to give near maximal growth when one is made limiting with respect to the normal excessive amount of the other. However, when the level of L-arginine is lowered to 20 μg , no growth occurs with 10 μg L-proline. Maximal growth is not obtained until levels of 400 μg L-arginine are approached. Similarly, when L-arginine is held at 20 μg , growth increases progressively until levels somewhat above 200 μg proline are reached. This inter-relationship is not found with any of the other 16 amino acids when the low level of proline is used. Studies on the possibility of inter conversion of these amino acids have thus far shown that ornithine is ineffective in replacing arginine for the organism's needs with limiting proline. Further studies on the mechanism of this interrelationship are in progress.

Purine ribose nucleotide inhibition of desoxyribonucleic acid utilization by *Lactobacillus bifidus* HELEN R SKEGGS,* LEMUEL D WRIGHT, KATHERINE VALENTIK,* HELGA NEPPLE* AND JOHN SPIZIZEN* *Med Research Division, Sharp & Dohme, Glenolden, Pa*

The ability of ribonucleic acid (RNA) specifically to inhibit the utilization of desoxyribonucleic acid (DNA) by *Lactobacillus bifidus* (*Lactobacillus acidophilus* ATCC #4963) was described by Skeggs *et al* (*J Am Chem Soc* In press). RNA, degraded by alkaline hydrolysis, retained

its inhibitory ability. Further investigations have been made to determine whether any of the known products of RNA degradation could substitute for RNA in inhibiting the utilization of DNA by *L. bifidus*. The purines and pyrimidines, ribose nucleosides, uridylic acid and cytidylic acid have no effect on the ability of *L. bifidus* to utilize DNA. The purine ribose nucleotides, adenylic acid (adenosine-3-phosphoric acid or adenosine-5-phosphoric acid) and guanylic acid, competitively inhibit the utilization of DNA by the organism. The effects of the purine nucleotides can be demonstrated either by the test tube assay procedure previously described or by filter disk plate assay techniques. When vitamin B₁₂ is substituted for DNA in the nutrition of *L. bifidus* the effects of the purine nucleotides cannot readily be demonstrated.

Cytochrome c reductase (DPN) of heart muscle particles E. C. SLATER (introduced by S. OCHOA) *Molteno Inst., Univ. of Cambridge, England*

The aerobic oxidation of reduced DPN (DPNH₂) by Keilin and Hartree's heart muscle preparation was completely inactivated by treatment with 2,3-dimercaptopropanol (BAL) in air. The oxidation was restored by the addition of methylene blue. The reduction of cytochrome *C* by DPNH₂ in the presence of heart muscle preparation and cyanide was also inactivated by BAL-treatment. Spectroscopic studies indicated that cytochrome *b* was not on the main pathway for the aerobic oxidation of DPNH₂ but is concerned in a slow anaerobic oxidation of DPNH₂ by fumarate. This reaction is also inhibited by BAL. It is concluded that the cytochrome *c* reductase (DPN) on the heart muscle particles contains at least two components, one of which (diaphorase) is unaffected by BAL and the other is the BAL-labile factor previously found in the succinic oxidase system, acting between cytochromes *b* and *c*. The endogenous cytochrome *c* on the heart muscle particles must be reduced by DPNH₂ or succinate at 1200 times the rate at which the same concentration of added cytochrome *c* is reduced (in the presence of cyanide) in order to account for the observed rate of aerobic oxidation in the absence of added cytochrome *c* or cyanide.

Mechanism of anticonvulsant action of 2-diethyl, 1,3-propanediol I. H. SLATER, D. E. LEARY AND J. F. O'LEARY (introduced by S. W. CLAUSEN) *Dept. of Pharmacology and Toxicology and Dept. of Surgery, Division of Orthopedics, Univ. of Rochester School of Medicine and Dentistry, Rochester, N. Y.*

It has been suggested that monoethers and substituted ketals of glycerol which cause flaccid paralysis without loss of consciousness inhibit

multisynaptic pathways, particularly in the spinal cord. These agents are effective in the protection of animals from death from metrazol and strychnine convulsions. More recently, Berger has reported that 2-diethyl, 1,3-propanediol (DEP) appears to be an unusually effective agent for the protection of mice from metrazol and strychnine convulsions. We have extended these studies to larger animals. Cats anesthetized with dial given intravenous doses of 50 mg/kg of DEP did not convulse after large doses of either strychnine or metrazol. Conversely, when convulsions were induced in such cats with these drugs, it was possible to control the seizures with DEP. Similar observations were made after intraperitoneal injection in unanesthetized cats and rabbits. In cats anesthetized with dial, the i.v. administration of DEP in doses as high as 153 mg/kg caused no change in the knee jerk or in the response of a muscle to nerve stimulation. Doses of 50 mg/kg intravenously caused a distinct transient decrease in the amplitude of the flexor reflex response, a finding indicative of inhibition of multineurone reflex arcs in the spinal cord. Rapid i.e. injection of DEP was followed by slowing of the heart rate, a drop in mean arterial blood pressure and a slowing or cessation of respiration, findings more marked in ether than in dial anesthesia. After fatal doses, circulation continued several minutes after cessation of respiration.

Competitive effects of substrates for hexokinase MILTON W. SLEIN (introduced by C. F. CORI) *Dept. of Biological Chemistry, Washington Univ. School of Medicine, St. Louis, Mo.*

The question has been investigated whether yeast and brain hexokinase have one or more active centers for the utilization of the 3 fermentable hexoses. The order of affinity for the yeast enzyme (from determinations of K_s , the substrate-enzyme dissociation constant) was mannose > glucose > fructose and this was also the order of mutual inhibition of utilization of these sugars from mixtures. For the pair glucose-mannose it was shown that K_i mannose was the same as K_s mannose and K_i glucose the same as K_s glucose, indicating that they act as substrates and inhibitors at the same center of the enzyme. With brain or yeast hexokinase there was nearly 100% inhibition of fructose utilization by an equimolar concentration of either glucose or mannose, while fructose had little inhibitory effect on the utilization of the aldo sugars. This strong inhibition is largely explained by the fact that the concentration of fructofuranose (which is the form with which the enzyme reacts) is only a small fraction of the total fructose concentration (roughly 20% in the above experiments). The predominant hexokinase in brain appears to be of the yeast type and the competitive effects of substrates

described above would explain why mannose but not fructose causes an immediate relief of hypoglycemia. Sugars which are not utilized by yeast or brain hexokinase (e.g. galactose) do not act as inhibitors. The fructokinase of muscle (Federation Proc 6 245, 1947) which does not act on glucose is not inhibited by this sugar. Enzymes which act on fructose-1-phosphate (probably the primary phosphorylation product of fructose by liver fructokinase) have been found in liver and muscle but not in brain.

Effect of diet upon urinary amylase excretion

BENJAMIN W SMITH* AND JOSEPH H ROE
*Dept of Biochemistry, George Washington Univ
School of Medicine, Washington, D C*

The effect of fasting and of diets high in carbohydrate, protein, fat, purine, and alkaline residue, upon the urinary amylase excretion was determined, using 156 medical students as subjects. A control 24-hour sample of urine with the subjects on their usual diet was collected. The subjects were then placed upon the experimental diet for 4 days and urine was collected during the final 24-hour period. The amylase content of the urine samples was determined by the method of Smith and Roe (*J Biol Chem* 170 53, 1949). Urinary nitrogen values were determined as a control upon the dietary intake. Statistical analysis of the data showed a highly significant decrease in the urinary amylase excretion on the high carbohydrate and alkaline residue diets and an increase of borderline significance on the high protein diets ($P = 0.13$) and on fasting ($P = 0.06$). These data suggest that the metabolism of carbohydrates decreases, and of proteins increases, the excretion of amylase in the urine.

Partition chromatography of the vitamin B₁₂ group of factors

E LESTER SMITH, W F J CUTHBERTSON, A WALKER AND K A LEES
(introduced by F S DAFT) *Research Division,
Glaxo Labs, Greenford, Middlesex, England, and
Fermentation Division, Glaxo Labs, Barnard
Castle, Co Durham, England*

We first obtained evidence of a second red clinically active anti-pernicious anaemia factor by partition chromatography of purified liver extracts with *n* butanol on columns of moist silica or starch. Subsequently we used strips or sheets of filter paper in place of the columns, following the separation of the red factors and coloured impurities visually, then (independently of WINSTEN AND EIGEN *J Biol Chem* 177 989, 1949) we developed an ultra-micro method whereby the factors were located by the 'zones of exhibition' induced on sheets of nutrient agar seeded with *L lactis* Dorner after contact with the developed strips and incubation. With this technique liver extracts and fermentation liquors gave 2 or 3 zones

of strong growth, and, further down the strip, one or more zones of diffuse growth. The substances responsible were tentatively identified by comparisons of R_f values with those of reference substances, using as solvents a range of higher alcohols and ketones. The order of separation with *n* butanol was (from slow to fast) vitamin B_{12b}, vitamin B₁₂ (giving dense zones), the desoxyribosides of cytosine, guanine, hypoxanthine, adenine, thymine (giving diffuse growth). By the visual technique, early samples of our own and of American vitamin B₁₂ gave a small slow-moving spot besides the main spot, but more highly purified English and American samples gave only single spots. By the ultra-micro technique, however, even these pure vitamin B₁₂ samples gave 2 (sometimes 3) zones on the agar, due to artefacts produced (presumably by oxidation) on the paper.

Solubilization and purification of cytochrome oxidase from heart muscle extract

E LUCILE SMITH* AND ELMER STOTZ *Dept of Biochemistry, Univ of Rochester School of Medicine and Dentistry, Rochester, N Y*

Cytochrome oxidase in heart muscle extract, commonly considered insoluble or associated with insoluble particulate material, has been prepared in a form which is not sedimented at 20,000 *g*. Pig heart muscle extract containing 0.8% sodium cholate was digested with crude trypsin or a fraction of fresh pancreas under carefully controlled conditions. This process increased the solubility of the oxidase, and the digest was subject to a fairly sharp fractionation of the enzyme with ammonium sulfate. The appropriate fraction was a clear brownish solution which had an oxidase purity about 7 times greater than the extract. The preparation contained approximately 3% ammonium sulfate and 0.5% sodium cholate. A further purification was effected by diluting the preparation to decrease the concentration of cholate and ammonium sulfate, then dissolving the precipitate formed in a mixture of ammonium sulfate and cholate. The cholate can be removed by dialysis against strong ammonium sulfate solution, and the enzyme remains in solution. The presence of ammonium sulfate was found to increase the solubility of cytochrome oxidase in the digested preparations, but not in the undigested heart extract.

Decomposition of chloramphenicol (chloromycetin) by bacteria

GRANT N SMITH AND CECILIA S WORREL (introduced by O D BIRD) *Research Labs, Parke, Davis & Company, Detroit, Mich*

An attempt has been made to determine the steps involved in the decomposition of chloramphenicol by bacteria sensitive to the drug using paper chromatography and chemical tests. The data from these studies indicates that there are

several possible pathways by means of which chloramphenicol can be degraded to compounds which no longer exhibit the strong antibiotic properties of the parent compound. At least 2 points of attack on the molecule are known with certainty. The aromatic nitro group may be reduced to an amine group or the amide linkage may be hydrolyzed with the formation of dichloroacetic acid and D(-)-threo 1-p-nitrophenyl-2-amino-1,3-propanediol. The order in which these reactions occur is determined by the individual organism. In the case of *E. coli*, the predominate reaction is the reduction of the nitro group of chloramphenicol to an aryl amine group. The amide linkage is then hydrolyzed with the formation of dichloroacetic acid and 1-p-aminophenyl-2-amino-1,3-propanediol. With other organisms such as *B. subtilis*, the chloramphenicol is hydrolyzed first to dichloroacetic acid and 1-p-nitrophenyl-2-amino-1,3-propanediol. The latter compound can then be reduced to 1-p-aminophenyl-2-amino-1,3-propanediol. Once the nitro group has been reduced to an aryl amine group no further change in this group appears to take place. No evidence could be obtained that the aryl amine group could be acetylated in the presence of ATP and acetate.

Proteolytic activity of rabbit muscle JOHN E. SNOKE* AND HANS NEURATH *Dept. of Biochemistry, Duke Univ. School of Medicine, Durham, N. C.*

Dilute KCl extracts of ground striated rabbit muscle exhibit proteolytic activity when tested against denatured hemoglobin as substrate. Activities were determined by incubating the extracts with the substrate for 1 hour at 35° and measuring the optical density of the supernatant solution at 280 mμ, after precipitation of the proteins by trichloroacetic acid. The proteolytic activity exhibits maximum stability at pH 6.0 and a sharp pH optimum at pH 4.0. Ferrous ions (0.04 M) cause a 5-fold increase in activity, manganese and magnesium being less effective in this respect. Zinc and barium ions, or cysteine, produce no activation. The amount of hemoglobin hydrolyzed is linear with time and the rate is proportional to the amount of extract used. Partial purification, with a concomitant increase in proteolytic activity, has been achieved by a process involving partial denaturation of the inactive proteins at 35° and fractional precipitation with trichloroacetate at pH 4. Active fractions thus prepared were, per mg. nitrogen, approximately 1/200 times as active at pH 4 as crystalline trypsin at pH 7.5.

Effect of advancing age on the cholesterol concentration of blood serum WARREN M. SPERRY AND MERRILL WEBB* *Dept. of Biochemistry, New York State Psychiatric Inst., New York City*
Recent reports of a marked increase in average

serum cholesterol concentration with advancing age (KELES, A. *Federation Proc.* 8: 523, 1949; GRAM, M. R. AND R. M. LEVERTON *Federation Proc.* 8: 384, 1949) are inconsistent with the hypothesis (SPERRY, W. M. *J. Biol. Chem.* 117: 391, 1937) that each individual maintains his serum cholesterol at a constitutional level from which large deviations do not ordinarily occur. Therefore, the cholesterol concentration of the serum was redetermined in most of the subjects of the investigation which led to this hypothesis, and which was carried out 13-15 years ago. In over half of the men no appreciable change in either direction from the earlier level was found. But in the remaining men and all but one of the women there were fairly substantial increases, ranging from about 10-30%. The average of the concentrations found in men in 1949 was 5.4% higher than the average obtained in the same subjects in 1934 to 1936, in women the corresponding value was 22.3%. The findings show that in some persons the serum cholesterol concentration is not maintained at as constant a level as had been thought, but they also indicate that an increase with advancing age is not obligatory. Changes in the method of determining cholesterol will be discussed in relation to the findings.

Studies of cellular calcifying mechanism ALBERT E. SOBEL, ALBERT HANOK* AND ALEXANDER WOLFFE* *Jewish Hospital of Brooklyn, Brooklyn, N. Y.*

Calcification *in vitro* of rachitic bones was used to further investigate the cellular mechanism of mineralization. Shaking rachitic rat sections with a solution containing 150 mEq/l of calcium chloride plus one of the following gave complete or almost complete inhibition of calcification, at a concentration of 2.5 mM/l of calcium and 0.161 mM/l of phosphate: 1) 0.1 mEq/l of beryllium chloride, 2) 0.5 mEq/l of cupric chloride, 3) 10.0 mEq/l of magnesium chloride, 4) 50.0 mEq/l of sodium chloride, 5) 100.0 mEq/l of strontium chloride, 6) 400.0 mEq/l of potassium chloride. Subsequent shaking with a solution containing 150 mEq/l of calcium chloride alone not only restored the calcifying power of the cells but increased the degree of calcification obtained under similar conditions before treatment of the sections. The inhibition due to beryllium was prevented by nickel chloride (5.0 mEq/l) and that of sodium by potassium chloride (5.0 mEq/l). Lower or higher concentrations of nickel and potassium were not as effective. The degree of inhibition of calcification appears to be a function of the ratio of calcium to the inhibitor indicating that this phenomenon obeys the Law of Mass Action.

Quantitative analysis of N¹⁵-labeled amino acids HERBERT A. SOBER,* MAX BRENNER* AND

JULIUS WHITE *Natl Cancer Inst, Natl Insts of Health, Bethesda, Md*

The investigation of nitrogen metabolism using N^{15} -labeled amino acids often depends on the isolation of pure amino acid fractions. A chromatographic procedure is described for the separation of some amino acids so that quantitative determinations of both the amino acid and isotope content may be performed. The procedure was designed for the determination of the amino acids in tissues. Conditions are described for the analysis of a mixture (ca 30 mg of nitrogen) consisting of aspartic acid, glutamic acid, glycine, alanine, urea and ammonia. The mixture is developed on a cation exchanger in the acid cycle (Dowex 50, 200-500 mesh), with increasing concentration of HCl. The effluent is divided into a regular series of small fractions (2 ml) with the aid of a fraction cutter. The constituent or constituents of each small fraction is determined by paper chromatography and the fractions combined accordingly. The combined fractions are analyzed for ammonia, nitrogen, etc and then analyzed for isotope content in the Consolidated Nier Mass Spectrometer. It is essential that at least a part of an amino acid appears uncontaminated with the component following it. The relative amounts of each constituent in a mixed fraction is determined by calculation using simultaneous equations containing the isotope content of each pure fraction. Recoveries of the components of synthetic mixtures have been obtained within 10% of theory. The application of this technique to the determination of free amino acids in tissue dialysates will be presented.

Effect of niacin on tryptophan requirement of the rat HARRY SPECTOR (introduced by HARRY L FEVOLD) *Nutrition Branch, Quartermaster Food and Container Inst for Armed Forces, Chicago, Ill*

Several investigators have stated that niacin increases the utilization of dietary tryptophan. The possible sparing of tryptophan by niacin has special nutritional significance in heat processed foods since it has been shown (PATTON, HILL AND FOREMAN *Science* 107: 623, 1948) that heat processing of foods in the presence of reducing sugars results in partial destruction of tryptophan. Effects of 3 levels of niacin (0, 2, and 10 mg %) were determined at 4 levels of tryptophan as provided by 6, 9, 12 and 18% of 'vitamin-free' casein. The nitrogen content of all the rations was made equivalent to that of 18% whole casein by the use of acid-hydrolyzed casein. The food intake of trios of rats, representing each level of niacin, was equalized during the first 4 experimental weeks. Five trios of Sprague-Dawley rats whose weights had been previously adjusted to about 66 gm were used at each level of tryptophan. At

all 4 levels of tryptophan the addition of niacin produced no greater gain in weight. The presence of niacin had no significant effect on the 24-hour urinary excretion of apparent-free tryptophan and nitrogen, at each tryptophan level. During the 5th and 6th weeks when all animals were allowed to eat *ad libitum* the addition of niacin, except at the level of 18% casein, resulted in a greater gain in weight associated with an increased food consumption. The significance of these data will be discussed.

Nutritional status of mice and their susceptibility to infection with *Shigella dysenteriae*

EUGENE M SPORN, EDWARD J SCHANTZ AND FRANK B ENGLE, JR (introduced by ALDEN K BOOR) *Camp Detrick, Frederick, Md*

Previous work in this laboratory (SCHANTZ SPORN AND ENGLE, Unpublished data) demonstrated that mice fed a semi-synthetic ration deficient in the vitamin B-complex were more susceptible to infection with *S. dysenteriae* than those fed a nutritionally complete ration. The present phase of the study was undertaken to determine whether individual vitamins were involved in this decreased resistance. Male weanling mice were fed diets lacking various members of the B-complex for extended periods, and then challenged with graded levels of *S. dysenteriae*. Mice fed diets deficient in riboflavin, pyridoxine, niacin, biotin or folic acid did not show any change in susceptibility to this organism. A thiamine deficiency was the only one of the 6 vitamin deficiencies examined which increased the susceptibility of mice. The lethal dose for mice on this deficiency was 1.2×10^5 organisms while the mice on the other rations required a dose of 1.2×10^8 . Experiments were conducted to examine the possibility that this increased susceptibility might be due to the emaciated condition of the mice. Pair fed controls for the thiamine deficient group, as well as mice restricted in food intake to drastically lower their weights, were maintained on a complete ration. There was no indication of an increased susceptibility in these animals. Mice that were fed a diet deficient in all members of the B-complex except thiamine showed no significant change in resistance. From these results, it is believed that thiamine is involved in some mechanism in the resistance of mice to *S. dysenteriae*.

Hormonal control of combination of insulin with isolated muscle W C STADIE, NIELS HAUGAARD* AND JULIAN B MARSH* *John Herr Musser Dept of Research Med, Univ of Pennsylvania, Philadelphia*

We have previously reported (*Am J Med Sc* 218: 265, 275, 1949) that the isolated rat hemidiaphragm, after a short preliminary equilibration in a medium containing insulin, utilizes glucose

and synthesizes glycogen at a greater rate than controls when equilibrated in a subsequent period in a medium containing glucose but no insulin. This was interpreted to mean that a chemical combination of insulin with structural units of the diaphragm takes place rapidly, that this combination is not easily reversed, and that the combined insulin exerts its customary effects on the metabolic pattern of the muscle. Furthermore, hormonal control of this chemical combination was indicated by the diminution of the reaction in the alloxan diabetic rat, and following injection of crude APE or crystalline growth hormone. Further studies on the hormonal aspects of this phenomenon are reported. Experiments on normal and adrenalectomized rats injected with purified growth hormone, ACTH, or adrenal cortical steroids, indicate that there is an interrelation between pituitary and adrenal hormonal factors in the regulation of the combination of insulin with muscle.

Coenzyme A-dependent transacetylation and transphosphorylation EARL R. STADTMAN (introduced by FRITZ LIPMANN) *Biochemical Research Lab, Massachusetts General Hospital, Dept of Biol Chemistry, Harvard Med School, Boston, Mass*

Extracts of *Cl. kluveri* contain a transacetylation enzyme which is measured by the catalysis of interchange of acetyl-bound with inorganic phosphate, using P^{32} (STADTMAN AND BARKER). This enzyme was considerably purified by ammonium sulfate fractionation. After several refractionations the enzyme becomes completely inactive but regains activity with the addition of coenzyme A (Co A). This purified fraction makes synthetic acetyl phosphate available as an acetyl donor to CO A-dependent liver acetyl-acceptor systems (acetoacetate, citrate and acetyl sulfanilamide synthesis). The fraction is free of ATP-acetate reaction. The apparent identity of the acetyl phosphate activating enzyme with the Co A-dependent transacetylation enzyme appears significant for the theory of acetyl transfer and of Co A function. A further surprising Co A-dependence was found with crude, resin-treated *Cl. kluveri* extract with reference to phosphate transfer from acetyl phosphate to propionate. The non-dependence of this reaction on adenylic acid was previously observed by Stadtmann and Barker, who studied this reaction. The Co A-dependent acetyl and phosphoryl-transfer functions appear in different protein fractions.

Preparation of 11-ketosteroids from methyl 3 α -acetoxy- Δ^9 11-cholenate HOMER E. STAEVELY (introduced by O. WINTERSTEINER) *Division of Organic Chemistry, Squibb Inst for Med Research, New Brunswick, N. J.*

Most of the methods for introducing the C_{11} -ketone group start with Δ^{11} 12-steroids. Hicks and Wallis (*J Biol Chem* 162 641, 1946) have reported the preparation of methyl 3 α -acetoxy-11-ketocholanoate from methyl 3 α -acetoxy- Δ^9 11-cholenate. In this paper the results of a similar investigation conducted in 1943 are reported. The semicarbazone of methyl 3 α -acetoxy- Δ^9 11-12-ketocholanoate was reduced by the Wolff-Kishner method to 3 α -hydroxy- Δ^9 11-cholenic acid, purified by chromatographing the crude 3 α -acetoxy methyl ester. After treatment with N-bromacetamide in aqueous acetone the total reaction product was debrominated with zinc-acetic acid. A product was isolated which appeared to be methyl 3 α -acetoxy-11-hydroxy- $\Delta^{8,9}$ -cholenate (Anal Calcd for $C_{27}H_{42}O_5$ C, 72.6, H, 9.5 Found C, 72.5, H, 9.8). This structure was proved by chromic acid oxidation to methyl 3 α -acetoxy- $\Delta^{8,9}$ -11-ketocholanoate (m.p. 145–148°, Anal Calcd for $C_{27}H_{40}O_5$ C, 72.9, H, 9.1 Found C, 72.4, H, 8.9) which had an absorption peak at 252 m μ , ϵ 5600. Only an $\alpha\beta$ -substituted $\alpha\beta$ -unsaturated ketone would absorb in this region. Thus debromination, rather than debromination, took place. When methyl 3 α -acetoxy- Δ^9 11-cholenate was reacted with N-bromacetamide and oxidized prior to treatment with zinc-acetic acid, a normal debromination occurred and methyl 3 α -acetoxy-11-ketocholanoate was isolated (m.p. 127–129°, $[\alpha]_D^{25} + 85^\circ$, Anal Calcd for $C_{27}H_{42}O_5$ C, 72.6, H, 9.5 Found C, 72.3, H, 9.3). Proof for this structure was obtained by hydrolysis of the acetoxy ester, re-esterification with diazomethane and chromic acid oxidation to methyl 3,11-diketocholanoate (m.p. 78–82°, Anal Calcd for $C_{25}H_{38}O_4$ C, 74.6, H, 9.5 Found C, 74.6, H, 9.6). The crude product would not crystallize until seeded with an authentic specimen.

Relation of the labile factor to the 'accelerator effect' of serum MARIO STEFANINI AND WILLIAM H. CROSBY (introduced by W. H. FISHMAN) *Ziskind Labs (Hematology Section) of Joseph H. Pratt and New England Center Hospitals and Dept of Medicine, Tufts College Med School, Boston, Mass*

One or more factors accelerating the conversion of prothrombin have been demonstrated in fresh serum. As some discrepancy exists on their nature and identity, it seems advisable to define them in terms of activity as 'serum accelerator effect'. While studying the relationship of these factors with other known coagulation agents, the concentration of the unconverted labile factor and the prothrombin activity were found inversely proportional to the accelerator effect in thrombin-free oxalated human serum. This was consistently observed in normal subjects and in patients with hemophilia, severe thrombocytopenic purpura or

under Dicumarol treatment Prothrombin activity was determined according to Quick *et al* (*J Lab & Clin Med* 34, 761, 1949), labile factor concentration according to Stefanini (*Am J Clin Path* In press) and accelerator effect of serum according to de Vries *et al* (*Blood* 4 247, 1949) Various amounts of bovine thrombin (from 0.5–10 Iowa units/ml) were then added to human fresh oxalated plasma, deprothrombinized according to Quick and Stefanini (*J Gen Physiol* 32 191, 1948) The serum thus obtained was incubated at 37° C for one hour, to assure complete neutralization of thrombin A marked accelerator effect developed in the sera Again the concentration of the labile factor was found to be inversely proportional to the accelerator activity Similar results were obtained with hemophilic and thrombocytopenic plasmas Our findings indicate that plasma contains the precursors of the agents responsible for the accelerator effect of serum One precursor is probably represented by the labile factor (factor V, plasma Ac globulin) and thrombin is required for its activation

Masking of carboxylate groups in native horse carbonylhemoglobin JACINTO STEINHARDT AND ETHEL M. ZAISER * *Dept of Chemistry, Massachusetts Inst of Technology, Cambridge, Mass*

'Titration curves' of carbonylhemoglobin are characterized by an anomalously high, almost abrupt increase in acid bound between pH 4 and 3, as compared with other proteins Since hemoglobin rapidly denatures in this region and back titration yields an entirely different curve, an effort has been made to determine the true titration curve by measuring pH and acid bound within 3 seconds after instantaneous mixing Data so obtained show only about one-third as much acid bound by carboxylate within this range as when otherwise determined The amount bound rises first very rapidly, and then much more slowly for some hours before attaining a stationary equilibrium value Changes in the increase in acid bound are paralleled, at each pH, by changes in the rate of simultaneous spectrophotometric effects The difference between the 3-second and long-time equilibrium curves reaches a maximum of 0.5 mm/gm by pH 3 It diminishes at lower pH where the liberation of titratable groups, and parallel spectrophotometric changes, proceed so rapidly that both techniques approach the same results Thus, at least 33 carboxylate groups, and probably many more, out of about 80 in this protein, are unavailable for combination with acid at pH below 4, until after exposure to acid (not necessarily below pH 4) has induced other changes The assumption that the liberation of all the unavailable groups is brought about by the binding of 2 protons by 2 of the initially available

carboxylates is shown to account for the observed phenomena

Sulfur-containing amino acids in growth with a 'labile methyl'-free diet containing vitamin B₁₂ JAKOB A. STEKOL, MARY A. BENNETT, KATHRYN WEISS,* PHILIP HALPERN* AND SIDNEY WEISS * *Lankenau Hospital Research Inst and Inst for Cancer Research, Philadelphia, Pa*

We reported previously that 30 days or older rats are able to grow on a diet which was free of all the known 'labile methyl group' donors but which contained vitamin B₁₂ and homocystine (*Abstracts, Am Chem Soc*, 116th meeting, Sept 18, 1949, 55C) The amino acid diet which was used in the above studies was complete with respect to all the essential amino acids, except for methionine, and it contained all the known vitamins, including folic acid and biotin We now find that on this diet, in the presence of vitamin B₁₂, homocystine produces even better growth response than equivalent amounts of homocystine Substitution of homocystine by L- and L-*allo*-cystathionine resulted in cessation of growth, which was resumed as soon as the cystathionines were replaced by homocystine On a diet containing ample methionine as the sole sulfur-amino acid, but which was free of vitamin B₁₂, poor growth was obtained, supplementing the methionine containing diet with vitamin B₁₂ resulted in good growth None of the experimental animals receiving vitamin B₁₂ died of kidney lesions in spite of the complete absence of 'labile methyl group' donors in the diet

Enzymatic synthesis of citric acid JOSEPH R. STERN* AND SEVERO OCHOA *Dept of Pharmacology, New York Univ College of Medicine, New York City*

The synthesis of citrate from oxalacetate, acetate (or acetoacetate), and ATP by enzyme solutions from pigeon liver has been previously reported (*J Biol Chem* 179 491, 1949) Both Lipmann's coenzyme A and Mg⁺⁺ or Mn⁺⁺ are required for activity Citrate, rather than *cis*-aconitate or *d*-isocitrate, is the product of the C₂ + C₄ condensation β -ketovalerate, β -ketocaproate, and β -ketooctanoate, like acetoacetate, can contribute a C₂ fragment for citrate synthesis in pigeon liver Citrate synthesis proceeds through at least 2 steps 1) ATP + acetate \rightarrow 'active' acetate, 2) 'active' acetate + oxalacetate \rightarrow citrate The 'active' acetate is closely related to acetyl phosphate The 'condensing enzyme' catalyzing step 2) is present in large amounts in yeast and in a variety of animal tissues (skeletal muscle, heart, liver, kidney, brain) It can be readily extracted with water and is relatively stable Both enzymes (1) and (2) are present in *E. coli* and *Azotobacter agilis* besides pigeon liver extracts

Preparations have been obtained from *E. coli* which contain a very active enzyme for step (1) but are almost devoid of condensing enzyme. Large amounts of citrate are synthesized when this preparation is combined with condensing enzyme from various sources.

Further studies on fractionation and photometric estimation of urinary estrogens BENJAMIN F. STIMMEL, *Rees-Stealy Med Research Fund, San Diego, Calif*

The hemipthalates of α -estradiol and estriol are quantitatively extractable from their ethyl ether solutions by aqueous potassium carbonate and sodium bicarbonate respectively. The esters produce typical Kober color products in proportion to their estrogen content. Advantage of these observations has been utilized to achieve additional purification of our chromatographic estradiol and estriol fractions (*J. Biol. Chem.* 162:99, 1946) from nonalcoholic contaminants. With the utilization of Girard's reagent T on our estrone chromatographic fraction, this modified procedure constitutes a more rigorous fractionation of the estrogens than can be achieved with our liquid chromatogram alone. The modified procedure is particularly effective in freeing nonpregnancy urinary estrogen residues (especially the estradiol fraction) from occasional purple pigments which cause overestimation of Kober titers. By this procedure comparative Kober and fluorometric (modified Jailer method) estrone, estradiol and estriol titers in human pregnancy urine generally are in good agreement. In nonpregnancy urine the fluorometric titers generally approximate one-third to one-half the corresponding Kober titers. There is evidence that nonestrogenic substances from the hydrolyzed urine are present in sufficient amounts to quench the full fluorescence exhibited by pure estrogens. By this procedure we have observed that the substance accountable for the Kober color product in pooled male urine to which had been added 16-ketoestrone immediately preceding zinc-hydrochloric acid hydrolysis cannot be 16-ketoestradiol nor estriol and is probably estradiol.

Relation of vitamin B_{12b} to vitamin B₁₂ and the biological activities of these compounds E. L. R. STOKSTAD, T. H. JUKES, JOHN A. BROCKMAN,* J. V. PIERCE,* H. P. BROQUIST* *Lederle Labs. Division, American Cyanamid Company, Pearl River, N. Y.*

Vitamin B_{12b} has been isolated from a fermentation product of *Streptomyces aureofaciens* as a red crystalline compound which exhibits different absorption spectra than vitamin B₁₂. The biological activities of vitamin B₁₂ and B_{12b} are the same for *Lactobacillus leichmannii* and for chicks. Catalytic hydrogenation of vitamin B₁₂ yielded

a compound which possessed the same ultraviolet, visible and infra red absorption spectra and the same biological activities for chicks and *L. leichmannii* as vitamin B_{12b}. These biological activities of the vitamin B₁₂ reduction product, described here, are in marked contrast to those of vitamin B₁₂, also produced by the hydrogenation of vitamin B₁₂ (KACZKA, WOLF AND FOLKERS *J. Am. Chem. Soc.* 71:1514, 1949). Vitamin B_{12a} was reported to be approximately 10-30% as active as B₁₂ for *L. leichmannii* and 30% as active for chicks. Evidence has been obtained which indicates that vitamin B₁₂ is involved in the methylation of homocystine to methionine in the chick. Chicks were placed on a ration composed of alcohol extracted soybean protein 25%, glucose 62.5%, cystine 0.2%, dimethylaminoethanol HCl, salts, corn oil plus vitamins A, D, and E, inositol, calcium pantothenate, niacinamide, riboflavin, pyridoxine, thiamine, pteroylglutamic acid, and biotin. On this diet, and in the presence of vitamin B₁₂, both homocystine and methionine were found to give a growth response. In the absence of vitamin B₁₂, only methionine gave a response while homocystine was without effect.

Nitrogen and ash content of soft tissues adjacent to bones and joints L. J. STROBINO (introduced by PAUL B. HAMILTON) *Dept. of Biochemistry, Alfred I. du Pont Inst., Nemours Fdn., Wilmington, Del. and Dept. of Orthopedic Surgery, Univ. of Pennsylvania, Philadelphia*

The present study represents a continuation of the investigations reported by Strobino and Farr (*J. Biol. Chem.* 178:599, 1949), on the nitrogen and ash content of beef and human bones. Analyses of calf bones showed an average of about 4.5% nitrogen and 67% ash on the dry weight. Samples of articular cartilage, tendon, ligament, periosteum and semilunar cartilage, carefully cleaned of extraneous material, were dried to constant weight and analysed for nitrogen and ash. Nitrogen was determined by the gasometric micro-Kjeldahl method of Van Slyke and ash was measured gravimetrically after heating in a muffle furnace at 600°C. Samples of the above tissues were taken from each of 10 calves less than 2 weeks old. All samples were taken from rear extremities between the knee and hoof. Averages of 10 determinations for nitrogen and ash as percentage of dry weight are as follows: articular cartilage, nitrogen 13.7, ash 7.0; tendon, nitrogen 17.1, ash 1.7; ligament, nitrogen 16.7, ash 1.9; periosteum, nitrogen 16.5, ash 1.4; semilunar cartilage, nitrogen 17.0, ash 1.6. As expected, these tissues show a much higher nitrogen and lower ash content than bone. Articular cartilage is intermediary in composition and the other tissues analysed show a remarkable similarity, with a high nitrogen and very low ash content.

Observations on plant amide enzyme system

P K STUMPF (introduced by H A BARKER)
Division of Plant Nutrition, Univ of California, Berkeley

An enzyme has been isolated from sugar pumpkin seedlings which specifically catalyzes the exchange reaction $\text{COOHCHNH}_2\text{CH}_2\text{CH}_2\text{CON}^{14}\text{H}_2 + \text{N}^{14}\text{H}_3 \leftrightarrow \text{COOHCHNH}_2\text{CH}_2\text{CH}_2\text{CON}^{15}\text{H}_2 + \text{N}^{14}\text{H}_3$. Since glutamylhydroxamic acid is formed when NH_2OH is substituted for NH_3 , the rate of its formation was employed for the majority of experiments to be reported. With either N^{14}H_3 or NH_2OH , the components of the system are 1) enzyme protein(s), 2) manganese, and 3) inorganic phosphate or arsenate. Manganese is the specific metal component. Mg, Zn, Cu, Co, Fe, Ba, and Al are ineffective. Furthermore, Zn and Cu are strong inhibitors of the system. The K_m value for Mn is about $2.5 \times 10^{-5} \text{ M}$. While phosphate or arsenate was found to be essential, ATP, ADP, and Co A could not replace them. Arsenate increased the rate of hydroxamic acid formation some 2-3 times above that of the phosphate system. Attempts to detect the accumulation of a glutamylphosphate intermediate in the enzyme reaction mixture in the absence of NH_2OH have failed. Further, glutamic acid, which should accumulate from a hydrolytic breakdown of the hypothetical phosphoryl derivative, could not be detected by paper chromatography in the reaction mixture. Finally, the enzyme is apparently highly specific for glutamine. The following compounds proved inactive: asparagine, glutathione, nicotinamide, pyrrolidone carboxylic acid, and glutamic acid.

Liberation of amino acids and active peptides from raw, heated and vitamin-free casein by tryptic digestion ROYAL A SULLIVAN, WILLIAM E DOWNEY, ELIZABETH K STANTON, ELIZABETH VAN WAGONER AND MARY JANE HANSELL (introduced by L K RIGGS) *Natl Dairy Research Labs, Oakdale, N Y*

The digestion of vitamin-free casein by enzymes has been studied by Pader, Melnick and Oser (*J Biol Chem* 172:763, 1948) after further dry heat treatment of the casein and by Hankes, Riesen, Henderson and Elvehjem (*J Biol Chem* 176:467, 1948) after further moist heat treatment, but in both cases the starting material may have been considerably altered from the protein found in milk. Casein pastes were prepared by acid precipitation of raw skim milk and washed in a supercentrifuge. After 6 days hydrolysis with Wilson's trypsin, it was found that 46% of the amino acids had been liberated from raw casein as compared with 35% from vitamin-free casein and 26% from commercial dried casein. Similarly, hydrolysates prepared from raw casein or from

vitamin-free casein contained only 11% of non-dialyzable nitrogen, while those prepared from commercial dried casein contained 18% of non-dialyzable nitrogen. The non-dialyzed residues were partially hydrolyzed by the addition of fresh trypsin. Microbiological assays of these hydrolysates for 18 amino acids showed distinct differences in the availability of individual amino acids from one type of casein to another. The total weight of available amino acids amounted to 78% for commercial dried casein, 77% for vitamin-free casein and 84% for raw casein.

Nucleotidases of liver MARJORIE A SWANSON (introduced by C ARTOM) *Dept of Biochemistry, Bowman Gray School of Medicine, Winston-Salem, N C*

The specificity of enzymes of the liver which split the nucleotides, especially adenosine triphosphate (ATP) has been investigated. The activity of two fractions of rat liver homogenate, the large granules or mitochondria, and the supernatant solution freed of granules, was tested against 4 substrates, at 5 pH values, both with and without added magnesium or calcium ions. Glycerophosphate and adenosine 3 monophosphate were more actively split by the supernatant than by the granules. The optimum pH was in the acid range. Adenosine-5-monophosphate (A-5-MP) was more actively split by the granules than by the supernatant. The activity was highest at neutral pH. Activity against these 5 substrates was little affected by the added ions. On the other hand, the rate of splitting ATP was about the same for the granules and the supernatant. The greatest activity was around pH 5.5 in the absence of added ions, and between 7.4 and 9 in the presence of Mg^{++} . At pH values above 5 the activity was also increased by Ca^{++} but not nearly to the same extent as by Mg^{++} . By fractional precipitation with $(\text{NH}_4)_2\text{SO}_4$ a precipitate was obtained which split ATP but not A-5-MP. Lysed human red cells also split ATP but not A-5-MP. More detailed studies on the partially purified liver preparation are in progress. From the results reported above, it appears that there is at least one specific enzyme splitting ATP. The effects of Mg^{++} , Ca^{++} and pH are specific for this enzyme and are not due to the action of these factors on other enzymes, such as A-5-MPase or non-specific phosphatases.

A study of the transamination reaction using isotopic nitrogen STUART W TANENBAUM* AND DAVID SHEMIN *Dept of Biochemistry, Columbia Univ, New York City*

An *in vitro* system employing pig heart breis has been used to study both the scope and mechanism of the transamination reaction. The addition of labeled amino acids and α -ketoglutarate to the

above with subsequent isolation and isotopic analysis of the products formed has enabled us to ascertain whether or not transamination has taken place. To serve as a model experiment, L-alanine (1.97% N^{15}) α -ketoglutaric acid, and non-isotopic ammonia in equivalent amounts were incubated with the pig heart breis at 37° at pH 7.4 for one hour. This experiment yielded L-glutamic acid (1.43% N^{15}) with practically the same isotopic content as that of the reisolated alanine (1.70% N^{15}). Samples of ammonia recovered had extremely low isotopic values, being of the order of 0.033% N^{15} . Thus it can be concluded that oxidative deamination coupled with reductive amination involving the transient formation of ammonia had not taken place, and that transamination via a Schiff's base type of intermediate has occurred. Similar experiments were performed with L-leucine as the isotopic amino acid. In this case, while the glutamic acid isolated had only roughly one-third the isotopic content of the recovered leucine, the N^{15} values of ammonia samples were negligible. This then demonstrates that leucine is capable of transamination with α -ketoglutarate. Further experiments with other labeled amino acids in this system are in progress. Using similar techniques, the role of the co-enzyme, pyridoxamine, in this process is also under investigation.

Synthesis of high molecular-weight protein-like substances by chymotrypsin HENRY TAUBER
Natl Insts of Health, Inst of Microbiology,
Lab of Antibiotic Research and Development,
U S Marine Hospital, Staten Island, N Y

It was recently found that an insoluble protein-like substance is synthesized when a small amount of chymotrypsin is added to a concentrated solution of Witte peptone. Such synthetic protein-like substances have now been produced from neutralized, protein-free concentrates of peptic digests containing about 45% solids on an ash-free basis of egg albumin, bovine albumin, fibrin and zein. No such action could be observed with crystalline trypsin. When 30 mg of crystalline chymotrypsin (in 4 cc of water) is added to 100 cc of the peptic digest of pH 7.3 and kept at 37°C , the solution turns viscous within a few hours and becomes a solid mass within 6 to 24 hours. With more chymotrypsin the reaction is more rapid. During peptic digestion, toluene is used as the antiseptic. During synthesis, sodium fluoride is employed. The synthetic protein-like substances contain a large number of different amino acids. They contain about 15.5% nitrogen. They are soluble in dilute acids and alkalis and form gelatinous precipitates on removal of these ions by dialysis. They are precipitated by protein precipitants and are insoluble at pH 4.0 to 8.5, with the exception of the zein product which is soluble between 6.2 and 8.5, and in more alkaline solutions.

The zein product is isoelectric close to pH 6.0. The average molecular weights of the synthetic products as determined in the analytical ultracentrifuge are estimated to be in the range 250,000–400,000. The protein-like substances are readily hydrolyzed by crystalline pepsin at pH 1.5, fairly well by crystalline chymotrypsin at pH 7.6, and less readily by crystalline trypsin at pH 7.6.

Specific volumes and molecular weights of D-glyceraldehyde phosphate dehydrogenase and aldolase JOHN FULLER TAYLOR *Dept of Biological Chemistry, Washington Univ School of Medicine, St Louis, Mo*

The partial specific volume, \bar{V} , of a protein is needed in order to calculate molecular weight from sedimentation and diffusion. We have investigated the use of the gradient tube of Linderström-Lang to measure the densities of protein solutions, concentrations of which were determined from dry weights. The requisite quantities of protein are small, the determination of density can be made as sensitive as desired, and labile enzyme proteins can be studied at low temperature to retard denaturation. As a test of the method, \bar{V}_{20} for human oxyhemoglobin was found to be 0.749, for crystalline bovine serum albumin (Armour) 0.734, corresponding to 0.749 and 0.736 found in the literature. For crystalline D-glyceraldehyde phosphate dehydrogenase (1) and aldolase (2) from rabbit muscle, \bar{V}_{20} by this method = 0.737 and 0.740 respectively. \bar{V}_{20} has also been calculated from the amino acid composition of these enzymes (VELICK AND RONZONI *J Biol Chem* 173:627, 1948) using the volume increments of the amino acid residues (COHN ET AL *J Biol Chem* 100:Proc LVIII, 1933). For both, the calculated \bar{V}_{20} = 0.743. The difference in the case of (1) may be related to the presence in the crystalline enzyme of diphosphopyridine nucleotide. Molecular weights calculated with these data are close to 118,000 (1) and 147,000 (2).

Factors affecting glycogen formation in vitro

CHING-TSENG TENG,* F MAROTT SINEX,* AND A BAIRD HASTINGS *Dept of Biological Chemistry, Harvard Med School, Boston, Mass*

The following medium has been used to study glycogen formation by rat liver slices *in vitro* from glucose and/or pyruvate. $K = 110$, $Mg = 20$, $Ca = 10$, $HCO_2 = 40$, $Cl = 130$ mV per liter. When pyruvate was present, it was substituted for an equivalent amount of Cl . A comparison of the amount of glycogen formed when the added substrates consisted of only glucose, only pyruvate, or mixtures of the two (all with equal concentrations of substrate carbon) showed that mixtures of the two substrates resulted in more glycogen than either one alone. The sources of the glycogen carbons were studied using glucose

uniformly labeled with C^{14} , prepared by Dr Martin Gibbs, and pyruvate labeled with C^{14} in the carbonyl carbon, prepared by Dr Manfred L Karnovsky. It was found that with labeled glucose or labeled pyruvate only as substrate, 80% of the resulting glycogen carbons were derived from the added substrate. By comparing experiments with a) labeled glucose plus unlabeled pyruvate and b) unlabeled glucose plus labeled pyruvate, it was found that about 40% of the glycogen carbon was derived from glucose carbon and about 36% from pyruvate carbon. Livers from adrenalectomized animals had an increased capacity to form glycogen from both glucose and pyruvate, whereas livers from diabetic-adrenalectomized animals had a diminished capacity to form glycogen from glucose but not from pyruvate.

Isolation of crystallized acetal phospholipid from brain S J THANNHAUSER, N F BONCODDO* AND G SCHMIDT *Tufts College Med School, Boston, Mass*

Ten pounds of calf brains are dehydrated with acetone and extracted with alcohol at 37°. The vacuum dried extract is extracted with petroleum ether, the dried supernatant is saponified with N NaOH (37°, 5 days). Acetic acid is added to pH 5, the solids are exhaustively washed with acetone and extracted with ether. A dilute methanol solution of the dried extract is precipitated with lead subacetate and ammonia. The supernatant is treated with anion exchanger after removal of the lead. The solution of the dried supernatant in ethanol is precipitated with Reinecke salt and shaken with Ag_2O . The alkaline filtrate is decolorized with charcoal and evaporated after treatment with H_2S . The acetone extracted material is dissolved in methanol, the solution is treated with cation exchanger and dried. The solution of this material in 5 volumes of propanol crystallizes in the refrigerator. Recrystallization from methanol after another treatment with cation exchanger yields 0.4-0.7 gm of acetal phospholipid. M.P. (decomp) 205°, softening 80°, sintering 150° C. 57.4%, H 9.88%, N 3.9%, P 6.75%. 2,4-dinitrophenylhydrazones of the liberated aldehyde M.P. 106-107° (Palmityl aldehyde 109-110°).

Influence of dietary protein on glutamine content of rat tissues HENRY TIGERMAN* AND ROBERT W MACVICAR *Dept of Agricultural Chemistry Research, Oklahoma Agricultural Exper Station, Stillwater*

Replacement of protein (20% casein or soybean sodium proteinate preparation) in the diet of the rat by zein caused a pronounced increase in the glutamine levels observed in liver, lung, kidney, heart, spleen, muscle and brain tissues. Supplementation of the zein containing ration with

tryptophan did not produce any material decrease. Replacement by casein of 50% of the zein, however, reduced the glutamine values to the basal level. In a series of analyses carried out on the tissues the results shown below were obtained (mg glutamine/100 gm fresh tissue).

	CASEIN	ZEIN-CASEIN	ZEIN
Liver	88	94	156
Lung	82	86	165
Kidney	107	111	192
Heart	203	210	297
Spleen	168	165	268
Muscle	170	178	253
Brain	77	82	116

In addition to these results, elevated glutamine levels have been found in tissues of rats which have been starved, fed a ration devoid of protein or an adequate ration containing 0.25% iodinated casein (Protamone). These data suggest a positive correlation between tissue glutamine content and the rate of body protein catabolism.

Effect of pteroylglutamic acid on the incorporation of radioactive glycine in chick liver homogenates JOHN R TOTTER, BARBARA KELLEY,* PAUL L DAY AND RAYMOND R EDWARDS* *Dept of Biochemistry, University of Arkansas School of Medicine, Little Rock, and the Inst of Science and Technology, Fayetteville*

In vitro experiments were conducted with glycine containing C^{14} (approximately 10 microcuries/mg) in the carboxyl group. Livers from chicks which had been maintained for 3½ weeks on a purified diet containing either 0 or 200 γ /100 gm of PGA were used. The procedure of Winnick and associates (*Arch Biochem* 21:235, 1949) for determining the uptake of radioactive glycine was followed. Liver homogenates were incubated with the labeled glycine for 60-90 minutes and the radioactivity of the phospholipid extracts and protein residues were then determined. Phospholipid extracts from liver homogenates of deficient chicks averaged 10.3 counts/minute/mg of phospholipid, while those from positive control birds averaged 21.2 counts/minute/mg. Determinations of the phospholipid phosphorus indicated that the positive control birds had only slightly higher phospholipids than did the deficient chicks. The protein residues showed surprisingly low counts, those from deficient chicks averaging 0.55 counts/minute/mg protein while the positive controls averaged 1.46 counts/minute. The *in vitro* addition of PGA had little effect on the rate of incorporation of radioactive glycine in either phospholipid or protein of the homogenate.

Estimation of blood ergothioneine concentration by the determination of bromine-labile sulfur OSCAR TOUSTER (introduced by WILLIAM J

DARBY) *Division of Nutrition, Depts of Biochemistry and Medicine, Vanderbilt Univ School of Medicine, Nashville, Tenn*

Ergothioneine has long been known to be a constituent of mammalian red blood cells, but its physiological significance has not been established. An approach to this problem would be a study of factors affecting its concentration in blood. Since the modified uric acid method of Behre and Benedict (*J Biol Chem* 82:11, 1929) and the diazo reaction of Hunter (*Biochem J* 22:4, 1928) are considered to have limitations in specificity and reliability (Behre *Biochem J* 26:458, 1932; Latner *Biochem J* 42:xxxv, 1948), we have developed a procedure differing in principle from previous methods used to determine blood ergothioneine concentrations. It is based upon the bromine oxidation of the sulfur of ergothioneine into inorganic sulfate and the subsequent colorimetric determination of the sulfate. The analysis involves the following steps: 1) saline-washed erythrocytes are heated with uranium nitrate solution to yield a colorless, protein-free extract, 2) the extract is treated with bromine for 30 minutes and the excess bromine removed by aspiration, 3) the sulfate is precipitated as benzidine sulfate, 4) the precipitated benzidine is determined colorimetrically with sodium β -naphthoquinone-4-sulfonate. Inorganic sulfate and thiocyanate, which respond to this test, are present in negligible amounts in the extracts. Recoveries average 70% and duplicate analyses on different samples of the same blood are in fair agreement. The determination can be run on 1.5 cc of blood and is being employed to study ergothioneine blood levels in man.

Cholesterol esterase of rat intestinal mucosa

C. R. TREADWELL, LEON SWELL* AND J. E. BYRON* *Dept of Biochemistry, George Washington Univ School of Medicine, Washington, D. C.*

Highly active esterifying and hydrolyzing cholesterol esterase systems have been demonstrated in glycerol-water (1-1) extracts of rat intestinal mucosa by methods previously developed in this laboratory (*J Biol Chem* 180:615, 1949; 182:479, 1950). Depending on the substrate present, the enzyme catalyzed the synthesis or hydrolysis of cholesterol esters. The experiments indicated that the enzyme was a constant component of the mucosa of normal rats and was not removed by prolonged washing of the lumen of the intestine with saline under pressure. The hydrolyzing and esterifying systems had the same properties and characteristics as those of the pancreas. Bile salts were an essential component of both systems. The activities were not influenced by the substitution of citrate for phosphate buffer in the substrate mixtures. The cholesterol content of the

previous diet did not influence the occurrence or amount of the enzyme. A comparison of the enzyme activity in the mucosa of normal rats with rats with 95% of the pancreas removed suggested that the pancreas was the primary source of at least a major part of the cholesterol esterase of the mucosa.

Protein permeability through thin organic layers

H. J. TRURNIT (introduced by DAVID B. DILL)
Med Division, Army Chemical Center, Md

A. Rothen (*J Biol Chem* 168:75, 1947) found specific reactions in immunological systems where antibody and antigen are separated by inert, supposedly impermeable, materials. He suggested the existence of hitherto unknown molecular forces between large molecules. In order to uncover the mechanism of Rothen's effect, we repeated his experiments and obtained identical results. We then changed the physical pattern of the screening material, using multiple Formvar screens instead of single cast screens. A similar approach was made by Singer (*Federation Proc* 8:251, 1949). We found that multiple screens inhibit the specific reaction more than single cast screens of the same total thickness. Also, colloidal screens are more effective than Formvar screens. We then realized that so far no control had been made on the action of phosphate buffer itself. This has been the diluting agent for sera and antisera in Rothen's experiments as well as in ours. The control experiment proved that this buffer removes part of the antigen through the screen whereas distilled water, saline solution or veronal buffer have no such effect. The antigen penetrates the screen and can be transferred to a conditioned control plate. This plate shows a specific adsorption after treatment with antiserum, whereas the original plate gives correspondingly less adsorption. These results offer a simple explanation for Rothen's effect. A new technique developed during this study will be outlined.

Blood sugar and serum inorganic phosphate after the ingestion of D-glucose, D-fructose or D-xylose

D. A. TURNER (introduced by A. B. MACALLUM) *Dept of Biochemistry, Univ of Western Ontario, London, Canada*

Changes in the concentration of serum inorganic phosphate and of the concentration of the appropriate carbohydrate in the blood of normal human subjects have been determined after an oral dose of D-glucose, D-fructose or D-xylose. For each sugar there was a characteristic change in the concentration of serum inorganic phosphate. Changes in the concentration of blood xylose after xylose administration were much more reproducible than either the changes in the concentration of glucose after a test dose of glucose, or changes

in the concentration of fructose after a test dose of fructose Tween 80 (Sorbitol) had no effect on the serum inorganic phosphate or blood carbohydrate when given by mouth at the same time as the test dose of glucose. Similar results were obtained for fructose and xylose. These findings are discussed from the point of view of the possible metabolism of xylose and its possible phosphorylation during absorption. The xylose tolerance test would appear to be a much better test of absorption from the gastro-intestinal tract in man than either the glucose or the fructose tolerance test.

A micro technique for identification of organic compounds using isotopic indicators and paper chromatography SIDNEY UDENFRIEND (introduced by MILDRED COHN) *Dept of Biological Chemistry, Washington Univ Med School, St Louis, Mo*

Isotopic indicators and paper chromatography, as used in the isotopic derivative method of amino acid analysis, can be employed for rigorous identification of microgram quantities of compounds. A reagent is synthesized in two isotopic forms, with isotopes that can be determined accurately, one in the presence of the other. The unknown substance and the compound being used for comparison are converted to derivatives of the reagents, each with a different isotope. The two derivatives are then mixed and subjected to chromatography on paper. If the two derivatives are identical then one band results in which the proportions of the two isotopes remain constant throughout. This is ascertained by cutting the band into consecutive transverse strips and measuring the isotope proportions in each. If the substances are not identical then the isotope ratio will vary from one end of the band to the other. The technique has been applied to the identification of a substance isolated from paper chromatograms of tissue extracts, having an R_f similar to γ -aminobutyric acid. An authentic sample of S^{35} labelled pipsyl γ -aminobutyric acid was mixed with the I^{131} labelled pipsyl derivative of the unknown. One band resulted with ratios of I^{131} to S^{35} of 0.433, 0.449, 0.439, 0.433, in consecutive strips. A mixture of S^{35} -pipsyl leucine with I^{131} -pipsyl isoleucine yielded one band with ratios of 3.35, 2.23, 1.90, 1.83, 1.38, in consecutive strips. Similarly, S^{35} -pipsyl valine and I^{131} -pipsyl norvaline yielded one band with consecutive ratios of 0.078, 0.136, 0.253, 0.498, 1.07, 1.26, 3.17.

Influence of cortisone on proline oxidation W W UMBREIT AND N E TONHAZY * *Merck Inst for Therapeutic Research, Rahway, N J*

Proline oxidation by unwashed isotonic rat kidney homogenates is markedly decreased by the second day after adrenalectomy and remains at a low level thereafter. Treatment of the adrenalectomized animals (maintained on saline) with 0.5 to 1 mg cortisone daily maintains the activity of the proline oxidizing system or restores it to normal if treatment is instituted even weeks after adrenalectomy. The proline is oxidized to glutamate which is oxidized to completion via the tricarboxy acid cycle. Adrenalectomy and cortisone treatment do not markedly affect the ability of kidney homogenates to oxidize glutamate or other members of the cycle. The effect of cortisone appears to be primarily upon the level of the proline oxidizing enzyme. In adrenalectomized animals, the rate of proline oxidation is related to the amount of cortisone supplied.

Carbon dioxide fixation in dicarboxylic acids M F UTTER *Dept of Biochemistry, Western Reserve Univ School of Medicine, Cleveland, Ohio*

Previously it has been shown that pigeon liver preparations incorporate CO_2 in oxalacetate in the presence of ATP. Ochoa and collaborators have shown fixation of CO_2 in L-malate by a malate-TPN enzyme also obtained from pigeon liver. The relationship of these two processes is not understood. By examining the relative specific activities of the two acids after CO_2 fixation under various conditions an insight into the problem has been obtained. When dialyzed pigeon liver extracts are incubated with $C^{14}O_2$, oxalacetate, malate, and ATP, the specific activity of the oxalacetate is 3-4 times that of malate after short incubations. The ratio approaches 1 after longer incubation, presumably through the action of DPN-malic dehydrogenase. Prior treatment of the extract with a brain preparation capable of destroying DPN increases the specific activity ratio of oxalacetate to malate to 9. These results make it very unlikely that malate is a precursor in the fixation of CO_2 in oxalacetate. However, when TPN is substituted for ATP, the converse situation occurs with the specific activity of malate 3-4 times that of oxalacetate after short incubations and an approach to 1 after longer incubation. The foregoing results may be explained by either of the two following hypotheses: a) two separate mechanisms for CO_2 fixation exist, an ATP-dependent system for oxalacetate and a TPN-dependent system for malate, b) CO_2 is fixed in some intermediate compound which may be directed toward oxalacetate by ATP or toward malate by TPN.

A semi-micro synthesis of C^{14} -carboxyl labeled acetate J T VAN BRUGGEN,* CECIL K CLAY COMB,* TYRA T HUTCHENS,* AND EDWARD S WEST *Dept of Biochemistry, Univ of Oregon Med School, Portland*

Previously described syntheses of acetate by carbonation of a methyl grignard reagent have

generally involved macro quantities of reagents. In addition, specialized equipment not generally available to the small isotope laboratory has been required. An apparatus (slide 1) is described, which is easily assembled by a semi-skilled glass blower from inexpensive, readily available parts. The other essential equipment required is a water aspirator and a small liquid nitrogen cooling bath or its equivalent. Using the technique presented, $\frac{1}{2}$ to 1 millimolar quantities of carboxyl labeled acetate can be synthesized in 85 to 90% yields in a minimum of time. By controlled timing and addition of reagents in the completely closed system, a good yield of product is assured, and complete control of the isotopic agent is maintained. The apparatus may be adapted readily to the synthesis of many other similar products.

A modified method of estimation of xanthine oxidase activity in tissue homogenates J. C. VAN METER AND J. J. OLESON (introduced by I. S. DANIELSON) *Lederle Labs. Division, American Cyanamid Company, Pearl River, N. Y.*

In the course of testing the effect of diet on rat liver xanthine oxidase using the method of Axelrod and Elvehjem (*J. Biol. Chem.* 140: 725, 1941), some anomalous results were obtained. A number of 'zero' livers similar to those described by Richert, Edwards and Westerfeld (*J. Biol. Chem.* 181: 255, 1949) were found. This phenomenon was attributed to the presence of endogenous substrate in the liver and a low enzyme concentration. It was possible by the use of 2-amino-4-hydroxy-6-formylpteridine (AHFP) as a specific xanthine oxidase inhibitor (Lowry, Bessey and Crawford *J. Biol. Chem.* 180: 399, 1949) to negate the effect of the endogenous substrate present in the liver. Factorial experiments to determine the effect of AHFP, hypoxanthine, xanthine and the time interval after addition of substrate were performed. It was found that AHFP as an inhibitor and hypoxanthine as a substrate, alone and in conjunction, produced statistically significantly higher enzyme titers than those obtained by the original method. The mean rate of oxygen uptake approaches a maximum forty minutes after addition of substrate and remains approximately constant for the next sixty minutes. This latter corresponds to the linear part of the curve of oxygen uptake versus time after addition of substrate, used by Axelrod and Elvehjem for the calculation of enzyme activity. On the basis of the above findings, a modified method for the estimation of xanthine oxidase activity in tissue homogenates is proposed.

A comparison of D-3, glyceraldehyde phosphate dehydrogenase from yeast and from skeletal muscle SIDNEY F. VELICK AND SIDNEY UDEN-

FRIEND * *Dept. of Biological Chemistry, Washington Univ. Med. School, St. Louis, Mo.*

That configurational differences exist between glyceraldehyde phosphate dehydrogenases crystallized from yeast and from rabbit muscle is shown by the demonstration of Krebs and Najar that they are immunologically distinguishable. We have analyzed the yeast enzyme for several amino acids by microbiological procedures for comparison with previous analyses of the muscle enzyme by Velick and Ronzoni. In addition we have carried out parallel analyses of several amino acids by the isotope derivative indicator method of Kesten, Udenfriend, and Levy on enzymes from the two sources. Some of the results are summarized as gm/100 gm protein. The first figure is for muscle, the second for yeast: GLU 5.7, 4.2, ASP 10.1, 9.4, ALA 7.1, 7.3, GLY 5.9, 4.9, PRO 3.4, 3.9, METH 2.7, 2.8, VAL 12.0, 11.2, ARG 5.2, 6.0, HIS 5.0, 3.5, LYS 9.4, 10.7, THR 5.2, 6.0, SER 4.4, 4.7, AMIDE N 0.95, 0.72. In both proteins there is a considerable excess of free basic over free acidic groups and yet both proteins are isoelectric in phosphate buffers in the acid region. This apparent anomaly is due to the strong affinity of the enzymes for phosphate ions. The characteristic features in composition of the muscle enzyme are shared by the enzyme from yeast. However, many of the differences observed are significant and it may be concluded, in agreement with other evidence, that the two proteins are similar but not identical. The terminal amino groups are being investigated.

Peptides released in the enzymatic conversion of ovalbumin to plakalbumin C. A. VILLEE, K. LINDERSTRØM-LANG* AND M. OTTESEN * *Chemical Dept., Carlsberg Lab., Copenhagen, Denmark.*

The conversion of ovalbumin to plakalbumin by an enzyme from *Bacillus subtilis* was discovered by Linderstrøm-Lang and Ottesen. In this reaction, approximately 1% of the protein is split off and appears as a mixture of peptides. By means of starch column chromatography these peptides and their hydrolysates were separated and analyzed. The peptides were obtained by precipitating the protein, after a given reaction period, with 10% trichloroacetic acid and extracting the TCA with ether. The aqueous solutions of peptides were then concentrated by lyophilization and aliquots were placed on columns. A variety of solvents were tried but for routine purposes a mixture of 1 butanol 2 n-propanol 1 0.1 N aqueous HCl followed by 2 n-propanol 1 0.5 N aqueous HCl was used. For the first 5 hours of reaction, the peptides upon hydrolysis yielded only alanine, valine, glycine and aspartic acid. No glutamic acid was found. When the unhydrolyzed pep-

tides were placed on columns they were separated into 3 distinct fractions, A, B, and C. The appearance of fractions A and C in the reaction is correlated with the ammonium sulfate titration, shown by Linderström-Lang and Ottesen to be a measure of the conversion of ovalbumin to plakalbumin. In contrast, fraction B is produced by a second step, not correlated with this conversion. The fractions isolated from one column were dried, hydrolyzed with 6 N HCl, and analyzed on other columns. Fraction C proved to contain alanine alone, fraction A contained all 4 amino acids in the ratio 3 alanine 1 valine 1 glycine 1 aspartic acid and fraction B contained the 4 amino acids in equimolar quantities.

Glutamo- and asparto-transferases HEINRICH WAELSCH, ERNEST BOREK, NATHAN GROSSOWICZ* AND MOGENS SCHOU* *Depts of Biochemistry, N Y State Psychiatric Inst and Columbia Univ, New York City*

Studies on the recently discovered enzyme systems (116th meeting, Am Chem Soc, Sept, 1949) which exchange the amide group of glutamine and asparagine with hydroxylamine have been continued. The enzymatic synthesis and splitting of γ -glutamo- and β -aspartohydroxamic acid occurs with washed cells and cell free extracts of several microorganisms, as well as with pigeon brain and liver homogenates. The enzymes were studied in detail in cell-free extracts of *Proteus vulgaris*. The addition of phosphate to extracts, dialysed for 48 hours, did not change the rate of enzymatic synthesis. The expected liberation of ammonia during the enzymatic synthesis is difficult to establish quantitatively since the extracts possess weak glutaminase and strong asparaginase activity. The pH dependence curve of glutamohydroxamic acid synthesis (optimum ca. 8) reflects only the pH dependence of the synthetic process. In the case of aspartohydroxamic acid the curve is a composite of the pH dependence of synthesis and of splitting, since the extracts show considerable activity in splitting aspartohydroxamic acid. Over the whole pH range studied there is no formation of chromogenic material, detectable with the ferric chloride reaction, if glutamine is replaced by glutamic acid. However, aspartic acid at low pH levels produces considerable chromogenic material. The enzymatic synthesis of glutamohydroxamic acid is inhibited by a variety of amino acids. The mechanism of this inhibition will be discussed.

Distribution of N^{15} in the amino acids of *Rhodospirillum rubrum* supplied N_2^{15} A C WAGENKNECHT* AND R H BURRIS *Dept of Biochemistry, Univ of Wisconsin College of Agriculture, Madison*

Seventeen amino acids and ammonia were separated quantitatively from an acid hydrolysate of *Rhodospirillum rubrum* cells by chromatography on starch columns. The most abundant amino acids were glutamic acid, alanine, valine, lysine, glycine, arginine and leucine-isoleucine. An illuminated culture of *R. rubrum* was grown for 3 days on a medium containing 20 mg/liter of ammonium nitrogen, malic acid was the carbon source. The culture then was aerated with N^{15} -enriched N_2 for 30 minutes. The cells were inactivated with acid, recovered and hydrolyzed with acid. The amino acids separated on a large starch column were analyzed for their N^{15} content. The compound showing greatest N^{15} enrichment was ammonia, followed by the alanine-glutamic acid mixture, aspartic acid and the leucine-isoleucine mixture. The monoaminomonocarboxylic acids and arginine were intermediate in N^{15} content and the lysine, histidine and cystine were lowest in N^{15} enrichment. This distribution of N^{15} among the amino acids of *R. rubrum* was very similar to that observed earlier when *Azotobacter vinelandii* was allowed to fix N^{15} -enriched N_2 .

Oxidation by cytochrome oxidase of reduced cytochrome c W W WAINIO, P PERSON, S J COOPERSTEIN AND B EICHEL (introduced by R H BARNES) *Bureau of Biological Research, Rutgers Univ, New Brunswick, N J, and Dept of Anatomy, Western Reserve Univ School of Medicine, Cleveland, Ohio*

A 'solubilized' preparation of cytochrome oxidase has been previously reported. The addition of 2% of sodium desoxycholate, and then 3% of sodium desoxycholate to the precipitate, followed in each instance by high-speed centrifugation, yields a preparation of high activity. The Qo-protein of the preparation used here was 2650 at 25°. The oxidation of reduced cytochrome c was followed spectrophotometrically and the effect of various factors studied. Phosphate buffers (Na_2HPO_4 - KH_2PO_4 , pH 7.4) at the highest concentrations studied (0.1 to 0.2 M final concentration) inhibited the oxidation. The rates at the lower concentrations (0.005 to 0.05 M final concentration) were constant. The effect of pH was studied in phosphate buffers of 0.033 M final concentration over the range 8.6 to 4.6 at intervals of approximately 0.2 of a pH unit. The pH optimum was at 6.67 ± 0.15 . Sodium desoxycholate inhibited the oxidation at concentrations approximately 75 times that added with the oxidase. Concentrations 37 times that added with the oxidase had no effect.

Effect of epinephrine on glucose uptake, glycogen formation and lactic acid production in isolated rat diaphragm OTTO WALAAS AND EYA WALAAS (introduced by G T CORI) *Dept of Biological*

Chemistry, Washington Univ School of Medicine, St Louis, Mo

Methods for the determination of microgram quantities of glycogen were reexamined. Owing to its solubility in 70% alcohol (about 6 $\mu\text{g/ml}$), serious losses of glycogen occur, unless alcohol volumes are kept below 1 ml and reprecipitation of glycogen is omitted. Diaphragms from rats of about 100 gm of body weight were soaked for 20 minutes in ice-cold Ringer's solution in order to remove preformed lactic acid. Of 2.84 mg of glucose taken up per gram of diaphragm per hour (average of 16 experiments), 48% were recovered as glycogen and 25% as lactic acid. In the presence of epinephrine (1 $\mu\text{g/ml}$ of medium), glucose uptake was 1.9 mg (average of 10 experiments), glycogen decreased 13% from its initial value and lactic acid formation increased 43% over that found in normal diaphragm, all statistically significant changes. O_2 consumption and R.Q. were not significantly different from normal. The low recovery (40% of glucose uptake) is probably the result of accumulation of hexosemonophosphate. Diaphragms of rats injected subcutaneously one hour previously with 0.02 mg of epinephrine showed a very low initial glycogen content, during incubation (in the absence of epinephrine) glucose uptake was slightly increased (3.22 mg, average of 10 experiments), glycogen deposition was not changed significantly from normal, while lactic acid formation was 20% below normal, a difference of marginal significance. These rather minor changes probably reflect alterations in the hormonal balance produced by the injection of epinephrine.

Synthesis of visual pigments from the retinenes

GEORGE WALD AND PAUL K. BROWN (introduced by J. T. EDSALL) *Biological Laboratories, Harvard Univ., Cambridge, Mass*

The light-sensitive pigment of rod vision, rhodopsin, is synthesized *in vivo* in two ways from the yellow products of its bleaching, retinene and protein, and from the colorless products, vitamin A_1 and protein. The regeneration from retinene₁ occurs slightly even in aqueous solution, though with a yield of at most 15% (Kühne, Hecht *et al.*). We have found that when cattle or frog rhodopsin in aqueous solution is flooded with synthetic retinene₁, it regenerates about 70% in the dark after bleaching by light. Rhodopsin is also synthesized by mixing its colorless protein moiety in aqueous solution with synthetic retinene₁. There is no evidence that other molecules participate in this reaction. It is a spontaneous, i.e. an energy-yielding process, the bleaching of rhodopsin requires energy, usually in the form of light. The synthesis is inhibited competitively by formaldehyde, and also by such retinene-

trapping reagents as hydroxylamine. When rhodopsin-protein is mixed in aqueous solution with synthetic retinene₂, a light-sensitive pigment is formed with its spectrum displaced in the direction of porphyropsin. Porphyropsin-protein, mixed with both retinenes, yields about the same results as rhodopsin-protein. These experiments in fact involve the synthesis *in vitro* of rhodopsin from crystalline vitamin A_1 , and of a comparable light-sensitive pigment from highly purified vitamin A_2 . The vitamins A were oxidized to the corresponding retinenes, not by a retinal process, but on manganese dioxide. The pathways of these syntheses however bear a significant relation to those which occur in the retina.

Isolation of crystalline conalbumin

ROBERT C. WARNER AND IONE WEBER * *Dept. of Chemistry, New York Univ. College of Medicine, New York City*

The conalbumin of the hen's egg white was first isolated in a purified form by Longworth, Cannan and MacInnes (*J. A. Chem. Soc.* 62, 2580, 1940). Their procedure entailed a precipitation below pH 4 in the presence of salt and was demonstrated to result in a product differing from the original protein in electrophoretic behavior. A method for isolating this protein without exposure to low pH has been reported by Bain and Deutsch (*J. Biol. Chem.* 172, 547, 1948) which yields an electrophoretically homogeneous, amorphous product. Conalbumin has now been obtained in crystalline form both as the ferric iron complex and as the iron free protein. The conalbumin was purified by salt and alcohol fractionation after the addition of excess iron. In most of this work, the filtrate from the usual crystallization of ovalbumin by ammonium sulfate was used as the starting material. Alcohol fractionation of egg white without prior removal of ovalbumin or globulins has also been employed. The purified protein was crystallized as needles or elongated prisms from 10% ethyl alcohol at the isoelectric point in the presence of 0.02 M sodium chloride. After removal of the iron, the protein can be crystallized in a different crystalline form by a similar procedure. The reddish brown crystalline iron complex contains two moles of ferric iron per mole of conalbumin. It is electrophoretically homogeneous above pH 4 in 0.1 ionic strength buffers.

Effects of narcotics and convulsants on rat tissue metabolism

JAMES L. WEBB* AND K. A. C. ELLIOTT *Montreal Neurological Inst., McGill Univ., Montreal, Canada*

The effects of a number of narcotic and convulsant drugs have been studied on the metabolism of isotonic suspensions of brain, of teased testis, and of kidney cortex slices, in bicarbonate

buffered medium. Accompanying the well-known inhibition of oxygen uptake of brain tissue by narcotics, a marked increase occurs in lactic acid formation. The rate of glycolysis increases with increasing narcotic concentration reaching a maximum when the respiration is inhibited 50 to 60%, and then decreases. The maximum may exceed the rate of anaerobic glycolysis. Total glucose utilization (calculated) is greatly increased. Under anaerobic conditions the glycolysis is not appreciably affected until the narcotic concentration is about the optimal for aerobic glycolysis. The concentration required for maximum aerobic glycolysis, 15 mM for sodium pentobarbital (Nembutal), varies from drug to drug but bears some relation to the narcotic potency of the drug. In the presence of Nembutal, succinate stimulates oxygen uptake but does not affect the glycolysis while ascorbate stimulates oxygen uptake and abolishes the extra aerobic glycolysis. L-glutamate oxidation was inhibited by Nembutal. Results with testis were similar to those with brain. With kidney cortex slices similar inhibition of respiration was obtained with or without glucose, and oxidation of L-glutamate, and the concomitant acid disappearance, were strongly inhibited. Metrazole, coramine and picrotoxin have little effect on brain tissue metabolism until a relatively high concentration is reached, when respiration is somewhat inhibited (60% with 50 mM metrazol) with very little increase in glycolysis.

Photochemical oxidation of amino acids, β -lactoglobulin and lysozyme in the presence of methylene blue. LEOPOLD WEIL AND JEANNE MAHER * *Eastern Regional Research Lab, Philadelphia, Pa*

Amino acids irradiated with visible light in the presence of traces of methylene blue undergo photo-oxidation to a varying degree. It was found by the manometric technique that tryptophane, tyrosine, histidine, methionine and cysteine were rapidly oxidized but the rest of the amino acids acted sluggishly or not at all. Irradiation of crystalline β -lactoglobulin resulted in complete disappearance of tryptophane and a parallel decrease in solubility when 16 mols of oxygen per mol of protein had been taken up. Tyrosine decreased only after the complete elimination of tryptophane. Results obtained with irradiated crystalline lysozyme strongly indicate that tryptophane is an essential part of this enzyme. Changes observed in the ultraviolet spectrum during irradiation were in line with the decrease of tryptophane and tyrosine. Under anaerobic condition, no reaction took place, indicating that these reactions were entirely due to oxidation.

An investigation of an electrophoretically homogeneous mucoprotein isolated from normal human plasma. HENRY E. WEIMER,* JOHN W. MEHL AND RICHARD J. WINZLER *Dept of Biochemistry and Nutrition, Univ of Southern California School of Medicine, Los Angeles*

A mucoprotein isolated from pooled, normal, human plasma by ammonium sulfate fractionation has been found to be electrophoretically homogeneous at pH values from 1.5-8.5. The material was found to be isoelectric at pH 1.8. The low isoelectric point is believed to be due to the presence of sulfuric acid ester groups in the molecule since there is an excess of sulfur over the cystine-cysteine and methionine content, and after mild acid hydrolysis of the material a positive test for sulfate can be obtained with barium chloride and benzidine reagents. This mucoprotein migrates with the α -1 globulins at pH 8.5 and can be demonstrated as a separate component in untreated serum at pH 4.5. At this pH it migrates toward the anode with a mobility of 4.2×10^{-5} CM²/sec/volt. Increased serum levels have been demonstrated electrophoretically in the serum of patients with cancer, with pneumonia, and with rheumatoid arthritis. This mucoprotein is a component of serum polysaccharides and of seromucoid investigated by other workers. Chemical analysis of the material yielded the following values: hexose-16.4%, hexosamine-11.9%, nitrogen-10.3%, lipid-3.6%, sulfur-1.02%, ash-1.8%. The amino acid composition as determined by microbiological assay is similar to that of the other plasma proteins. The molecular weight determined from analytical data is approximately 51,000.

Oxidation of isotopic palmitic acid in animal tissues. SIDNEY WEINHOUSE, RUTH H. MILLINGTON* AND MURRAY E. VOLK * *Research Inst and Dept of Chemistry, Temple Univ, Philadelphia, Pa*

Supplementing previous studies with short chain fatty acids, the metabolism of isotopically (carboxyl) labeled palmitic acid was studied in surviving animal tissues. In slices and whole homogenates of rat liver, and in washed homogenates supplemented with adenosine triphosphate, palmitate undergoes two metabolic transformations, complete oxidation to CO₂ and conversion to acetoacetate. Both processes are of approximately equal magnitude in contrast with the behavior of short chain acids which, under the same circumstances, are converted predominantly to acetoacetate. The labeled palmitate carboxyl carbon was found distributed approximately equally between the carbonyl and carboxyl carbons of acetoacetate. In washed homogenates fumarate in low concentrations enhanced the oxidation of palmitate as measured by incorporation of isotopic carbon in the respiratory CO₂.

and at the same time diminished production of acetoacetate. Oxidation of palmitate was observed in pigeon-breast and heart homogenates and in slices and homogenates of rat kidney and heart, but little or no oxidation occurred in rat brain or skeletal muscle homogenates. The data provide unequivocal evidence for extrahepatic oxidation of long-chain fatty acids and indicate that the enzymes which act on the higher fatty acids are the same ones responsible for the catabolism of the short-chain acids.

An enzymic approach to determination of crude fiber A WEINSTOCK AND G HARVEY BENHAM (introduced by MARTIN E HANKE) *Dept of Biology, Illinois Inst of Technology, Chicago, Ill*

The crude fiber content of foodstuffs as determined by the Weende method does not represent a true value because much of the indigestible matter is dissolved during the acid-alkali hydrolysis. Enzymic digestive methods have been found to give a close correlation to the digestibility or feeding value of the material under question. Methods suggested by Horwitt, Remy, Woodson, and others take from five to eight days for completion. A method is described using potent commercial enzyme preparations such as Rhozyme S and Polidase whereby values for the true indigestible matter are obtained in a reduced time interval. Starch is solubilized at pH 4.9 and 50°C in one hour, and protein in a further 20 hours. The digestion residues are filtered through alundum extraction thimbles, dried, weighed, ashed, and reweighed, the loss in weight being the crude fiber. Values of 4.0% indigestible matter were obtained in yellow corn meal compared with 0.9% by the Weende method. These results were duplicated using known mixtures. It is repeatedly found that the Weende method gives values about 3-4 times too low. Consequently the enzymic approach described gives values which are consistent with the actual content of indigestible matter by a method which is simple and readily adaptable to routine work.

Synthesis of labile methyl groups by animal tissues in vivo and in vitro ARNOLD D WELCH* AND WARWICK SAKAMI *Depts of Biochemistry and Pharmacology, Western Reserve Univ, School of Medicine, Cleveland, Ohio*

In previous work (Sakami and Wood, unpublished) the methyl carbon of acetone has been found to appear in labile methyl groups and to contribute to the formation of the formate or formate derivative from which the β -carbon of serine is formed. The formation of 'formate' from acetone suggested that synthesis of labile methyl groups might occur over this pathway. Conversion of formic acid to labile methyl has been ob-

tained in rats injected repeatedly with C^{14} -formate. The crude protein fraction was separated from the tissues and hydrolyzed with HI to release the methyl group of methionine as CH_3I , radioactivity of $(CH_3)_4NI$ formed from this was not altered by recrystallization. Rat liver slices were incubated in the presence of C^{14} -formate, homocysteine, dimethylaminoethanol, folic acid and vitamin B_{12} . After removal of unreacted $HCOOH$ and hydrolysis, methionine was isolated and degraded with HI, $(CH_3)_4NI$, with radioactivity unaltered by recrystallization, was obtained. Choline chloride, isolated from the slices via the reneckate and chloroplatinate, was converted to $(CH_3)_4N$ and recovered as $(CH_3)_4NI$ the radioactivity of which was unaltered by recrystallization. In progress are studies of homogenates and of the possible role of folic acid and vitamin B_{12} in the synthesis by various tissues of compounds containing methyl groups.

Ratio of sickle cell anemia to normal hemoglobin in sicklemics IBERT C WELLS AND HARVEY A ITANO (introduced by L ZECHNEISTER) *Gates and Crellin Labs of Chemistry, California Inst of Technology, Pasadena*

The discovery was made in these laboratories that the hemoglobin of persons having sickle cell anemia differs from normal hemoglobin and that both hemoglobins occur in persons with sickle cell anemia (Science 110 543, 1949). It was inferred that sickle cell anemia was inherited by an individual from sickle cell parents. The results of the genetic study of J V Neel (Science 110 64, 1949) are in accord with this conclusion. Since sickle cell anemia (SCA) hemoglobin and normal hemoglobin occur together in the erythrocytes of sickle cell persons, such individuals offer the possibility of studying the genetic control of hemoglobin synthesis. It was reported by us (Science 110 543, 1949) that in a pooled sample of blood from 5 sicklemics the SCA hemoglobin constituted 39% of the total. To ascertain whether this percentage is characteristic of sicklemics or not, the percentage of SCA hemoglobin in the blood of 20 sicklemics has been measured using the procedure previously employed. These were adult persons selected by chance. Among these individuals, the SCA hemoglobin composed from 24% to 43% of the total hemoglobin. Approximately one-third of the cases fell in the range 39% to 42%. From these results it appears that there is no ratio of the two hemoglobins which is characteristic of sicklemics. Factors which might affect the ratio are being studied.

Metabolism of intravenous testosterone in the human C D WEST* AND L T SAMUELS *Dept of Biological Chemistry, University of Utah College of Medicine, Salt Lake City*

Crystalline testosterone in serum albumin solu-

tion has been administered intravenously to several human subjects in doses up to 200 mg. Following this administration it is possible to measure and follow the blood levels of testosterone and its metabolites. The testosterone concentration in the blood decreases rapidly usually to zero during the first hour after injection. Approximately 60% of the administered testosterone can be accounted for as increased amounts of conjugated 17-ketosteroids in the urine during the first 24 hours. The peak excretion of urinary 17-ketosteroids occurs during the first 2 hours when an average of 30% is excreted. Small amounts of non-conjugated 17-ketosteroids can be demonstrated in these post-injection urines. Conjugated 17-ketosteroids can be demonstrated in the blood during this period of increased urinary excretion. Smaller amounts of non-conjugated 17-ketosteroids were also found in the blood. Conjugated α - β unsaturated steroids can be demonstrated in the urine for several hours after injection. In the immediate post-injection urines small concentrations of non-conjugated α - β unsaturated steroids are found. In patients with liver disease the rate of metabolism of intravenous testosterone is depressed.

Composition of rat liver xanthine oxidase and its inhibition by tetraethylthiuramdisulfide (antabuse) W. W. WESTERFELD, DAN A. RICHERT* AND RAYMOND VANDERLINDE* *Dept. of Biochemistry, Syracuse Univ. College of Medicine, Syracuse, N. Y.*

In vitro addition of tetraethylthiuramdisulfide (antabuse) to a rat liver homogenate inhibited its xanthine oxidase activity from 50% to 100%. Milk xanthine oxidase alone or when added to a liver homogenate containing antabuse was not inhibited. Methylene blue added to the aerobic system overcame the antabuse inhibition of the liver enzyme; dehydrogenation of xanthine was unaffected but autooxidation of xanthine oxidase was inhibited by antabuse. Heating the liver homogenate at 56° for 5 minutes destroyed the antabuse sensitivity of the xanthine oxidase without otherwise affecting the enzyme. Longer heating also reduced its capacity to react with atmospheric oxygen without affecting its dehydrogenase activity. Rat liver xanthine oxidase behaved as a single entity during its purification; the purified enzyme responded to antabuse, methylene blue, and 56° heating in the manner described for the enzyme in the homogenate. The results indicate that rat liver xanthine oxidase is similar to the milk enzyme, but is attached to some other constituent that confers antabuse-sensitivity upon the complex. By analogy with succinoxidase the possibility that this identified constituent is phospholipid is being investigated.

Succinoxidase activity was completely inhibited by antabuse and was destroyed by heating at 56° for 5 minutes. By contrast, the d-amino acid oxidase activity of a rat liver homogenate was not affected by antabuse, methylene blue, or heating at 56°C.

Xanthine metabolism in the rat J. N. WILLIAMS, JR.,* PHILIP FEIGELSON,* AND C. A. ELVEHJEM *Dept. of Biochemistry, College of Agriculture, Univ. of Wisconsin, Madison*

Liver xanthine oxidase activity in the rat has been observed to be highly dependent upon the level of dietary protein. This variation with diet offered a means of observing the relationship between *in vitro* and *in vivo* activity of this enzyme. Two groups of rats were given 6% casein and 18% casein + 0.25% methionine rations, respectively, for 3 weeks. The animals were then injected intraperitoneally with 25 mg xanthine per 100 gm body weight and the urines collected at intervals for one week. The animals were then killed for *in vitro* liver xanthine oxidase determinations. Allantoin excretion was determined in the urine collections to obtain an *in vivo* estimation of xanthine oxidase activity. Contrary to expectation, the rats with very low *in vitro* liver xanthine oxidase activity, (those fed the 6% casein ration) showed an output of allantoin about double that of the animals with normal liver activity. Moreover, the allantoin excretion accounted for less than 10% of the injected xanthine in both groups. Attempts to account for the injected xanthine as any of the purines both in urine and feces failed. Our results indicate that *in vitro* measurements of xanthine oxidase may not be an indication of the actual rate of xanthine oxidation in the intact animal. It appears that exogenous xanthine may be metabolized by a pathway other than that of simple oxidation to allantoin and subsequent urinary excretion.

Chromogenic values of ketosteroids in the Zimmermann reaction HILDEGARD WILSON (introduced by KONRAD DOBRINER) *Sloan-Kettering Inst. for Cancer Research, New York City*

The Zimmermann reaction is employed for the quantitative determination of individual ketosteroids isolated from human urine to establish steroid excretion patterns. Since various ketosteroids give different chromogenic values, the use of a single reference standard such as androstosterone does not give absolute values for the amounts of each steroid excreted. Therefore the relative intensities of ketosteroids commonly found in human urine were determined by the Zimmermann reaction as modified by Callow at 25°C and also by an adaption for micro amounts at 0°C. When the colors were developed at 25°C and read after 50 minutes the chromogenic values

relative to androsterone (=100) were as follows dehydroisoandrosterone, 100, Δ^2 or Δ^3 -androsten-17-one, 106, androstane-3,17-dione, 116, Δ^4 -androsterone-3,17-dione, 129, 11-hydroxyandrosterone, 62, etiocholanolone, 112, etiocholanone-3,17-dione, 114, Δ^5 -etiocholanolone, 117, 11-ketioetiocholanolone, 117, pregnan-3 α -ol-20-one, 15, and allopregnan-3 α -ol-20-one, 15. The results also indicate wide variations in the rates of reaction. Androstane-3,17-dione, etiocholanone-3,17-dione, Δ^5 -etiocholanolone and 11-ketioetiocholanolone have especially rapid color development. With both techniques the greatest similarity was found at the time of maximum color. Other results and experimental details will be discussed.

Incorporation of labeled amino acids into the protein of embryonic and tumor tissue homogenates THEODORE WINNICK *Radiation Research Lab, State Univ of Iowa Med School, Iowa City*
When homogenates of fetal rat liver or transplanted mouse mammary tumor were incubated with carboxyl- C^{14} -labeled glycine or alanine at 37° under oxygen atmosphere, the uptake of C^{14} by protein was several times as great as when homogenates of normal adult rat or mouse liver were employed. The turnover of glycine and alanine residues in the fetal liver and tumor homogenates was about 0.1 to 0.2% per hour. The incorporation process in the embryonic system was stimulated by adding certain members of the Krebs tricarboxylic acid cycle. Malonate was inhibitory. The isolated proteins lost no $C^{14}O_2$ when heated with ninhydrin. After complete acid hydrolysis all the C^{14} was released by ninhydrin. Protein from adult liver homogenate, incubated with glycine- C^{14} , lost most of its radioactivity upon subsequent treatment with dilute NaOH. The C^{14} was apparently concentrated in a labile peptide fraction, associated with this protein. By contrast, proteins from homogenates of fetal liver and tumor tissue retained their C^{14} when treated with alkali. The available evidence indicated that, in these systems, the C^{14} represented true incorporation of amino acids into protein structure.

Relation between propagation of mouse encephalomyelitis virus and uptake of radiophosphate by minced brain from mice RICHARD J. WINZLER, H. E. PEARSON* AND MAX E. RAFELSON* *Depts of Biochemistry and Nutrition, and of Microbiology, Univ of Southern California School of Medicine, and Lab Division of Los Angeles County Hospital, Los Angeles*

It has previously been shown that minced one-day-old mouse brain was capable of supporting the propagation of Theiler's GD VII mouse encephalomyelitis virus *in vitro*. Virus-infected cultures incorporate inorganic phosphate into

their phospholipids and nucleoproteins at rates significantly greater than uninfected controls. Minced brain from mice older than 10 days is unable to support virus growth. A study of the rates of oxygen consumption and of P^{32} uptake by minced brain tissue from mice of different ages in the presence and absence of virus shows that older mouse brain has a higher initial QO_2 than one-day-old brain, but the QO_2 declines at a very much more rapid rate than the one-day-old tissue. The incorporation of inorganic phosphate into the lipids and proteins in a 24-hour incubation period is much greater in the one-day-old brain than in older brain. The stimulating effect of the virus on these processes is no longer apparent in brain from mice older than 7 days, and corresponds to the ability of the tissue to support virus growth.

Location in protoporphyrin of carbon atoms derived from α -carbon of glycine and carbon atoms of acetic acid JONATHAN WITTENBERG* AND DAVID SHEMIN *Dept of Biochemistry, Columbia Univ, New York City*

It has been shown that 8 carbon atoms in protoporphyrin are derived from the α -carbon atom of glycine and that most or all of the remaining carbon atoms are derived from both carbon atoms of acetic acid. This paper presents experiments in which the positions of the carbon atoms in protoporphyrins derived from the α -carbon atom of glycine and from acetic acid are located. C^{14} -labeled hemin, prepared by incubating duck blood with C^{14} -methylene labeled glycine, was degraded by a procedure which allowed the isolation of individual carbon atoms. It was found that one-half of the total radioactivity of the porphyrin was present in the 4 pyrrole rings. Only the α -carbon atoms of the pyrroles on the same side as the vinyl and propionic acid side chains were labeled. The other one-half of the total radioactivity was accounted for by the methene bridge carbon atoms. From the data it is concluded that all 4 methine bridge carbon atoms are derived also from the α -carbon atom of glycine, that these carbon atoms have equal radioactivity and that their individual radioactivities are equal to the radioactivity of the individual labeled carbon atoms of the pyrrole rings. Also two samples of C^{14} -labeled hemin were prepared by incubating duck blood with carboxyl labeled acetate and with methyl labeled acetate separately. The locations of the carbon atoms which are derived from both carbon atoms of acetate will be presented. Hypotheses of porphyrin formation are discussed.

Requirements for organic phosphate in *in vitro* oxidation of 6-carbon fatty acids ROBERT F. WITTER (introduced by ELMER STOTZ) *Dept of Biochemistry, Univ of Rochester School of Medicine and Dentistry, Rochester, N. Y.*

By measurement of the rates of acetoacetate formation with properly fortified rat washed liver particles, the requirements for inorganic phosphate and adenine nucleotides for several 6-carbon acids, namely, hexanoate, 2- Δ -hexenoate, sorbate, β -hydroxyhexanoate, and β -ketohehexanoate, were investigated. In order to study the effect of high ATP concentration on the rate of sorbate oxidation, factors influencing the maintenance of the initial (added) ATP level were studied. An elevated 10-minute hydrolyzable phosphate level could be maintained using an enzymatic source of ATP, namely, a rabbit muscle protein fraction and 3-phosphoglycerate, whereas without the enzymatic source the initial level of ATP decreased to a low value. With the enzymatic source of ATP it was possible to use considerably higher concentrations of sorbate than under the usual conditions. Control experiments with added pyruvate showed that part of the above effects of the enzymatic source of ATP might be due to the enzymatic production of pyruvate from phosphoglycerate. Dinitrophenol blocked fatty acid oxidation and caused a decrease in the 10-minute phosphate to a low value, even with the enzymatic source of ATP. Under anaerobic conditions, where added pyruvate was ineffective, the enzymatic source maintained the level of 10-minute phosphate, and here again dinitrophenol caused the same effect as under aerobic conditions. This anaerobic effect of dinitrophenol is under further investigation.

Studies on tobacco chewing WM A WOLFF AND W E GILES * *Tobacco Research Lab, Bowman Gray School of Medicine, Winston-Salem, N C*

The purpose of this study was to determine the dosage and metabolism of nicotine resulting from the chewing of tobacco, and to compare the findings with determinations made after cigarette smoking. Experiments were made on 21 normal adult males, habitual tobacco users, who chewed during a test period of 6½ to 8 hours. Tobacco of known nicotine content was prepared from selected batches which had gone through all steps of the manufacturing process except being pressed into plug form. The nicotine content of the chewed tobacco and of the spittle was determined by the A O A C silicotungstate method, that of the blood and urine, by a method previously reported (*J Biol Chem* 175: 825, 1948). The difference between the nicotine content of the original tobacco sample and that of the spittle, including tobacco chewed, was considered as the amount of nicotine absorbed. The amount of tobacco chewed ranged from 15.6 to 58.4 gm, that of the nicotine absorbed, from 8.0 to 87.7 mg. Nicotine levels in the blood were determined before and after the period of chewing, and ranged from 0 to 0.56 mg/l. The increase during the chewing period averaged 0.05 mg/l, a value slightly lower than

those obtained with comparable doses of nicotine from smoking. The amount of nicotine excreted in the urine was 0.55-3.43 mg. Calculated as percentage of the total nicotine dose the excretion is about the same as found with cigarette smoking.

Effect of temperature on P^{32} transport in fertile and infertile eggs JEROME J WOLKEN (introduced by M A LAUFFER) *Dept of Biophysics, Univ of Pittsburgh, Pittsburgh, Pa*

Radioactive phosphorus as sodium phosphate was injected into the white of fertile and infertile hen's eggs and incubated at temperatures from 12° to 41°C for time intervals from 0 to 120 hours. The rates of transport were determined by a measure of activity and specific activity of P^{32} in the shell, white, yolk and embryo. It was found that P^{32} does not come rapidly to equilibrium between the white and yolk except in stored infertile eggs. The rates of change of activity in the fertile eggs are greater than those for the infertile eggs, and equilibrium is not established even after 120 hours at 41°C. Except for the first 9 hours of incubation, transport of P^{32} varies linearly with temperature, but is accelerated in the fertile eggs between 30° and 41°C, the optimum temperature range for enzymatic reactions and embryonic growth. The form of the equation at all temperatures in both the fertile and infertile systems is identical to that which describes the rate of a first order reaction. The velocity rate constant for the infertile system was found to be temperature dependent, and to behave as any ordinary physical transport phenomenon. But in the fertile system, the velocity rate constant is independent of temperature, and no mechanism has yet been postulated to explain this behavior. A theoretical interpretation of the processes of fertilization offers the possible explanation that the velocity rate constant varies with the effective volume of the yolk and the permeability of the yolk membrane.

Photosynthesis studies with isotopic CO_2 HARLAND G WOOD, GEORGE O BURR AND CONSTANCE E HARTT * *Dept of Biochemistry, Western Reserve Univ School of Medicine, Cleveland, Ohio, Experiment Station, H.S.P.A., Honolulu*

The photosynthetic fixation of isotopic CO_2 by beans, sugar cane and rye has been studied. The sugars from 80% alcohol extracts have been degraded by bacterial fermentation of the hexose unit. With sugar cane the 3,4 positions contained the highest, the 2,5 the next, and the 1,6 positions the lowest isotopic concentration and in general the relative difference was greater with shorter time of photosynthesis. With beans and rye the isotope in the 2,5 and 1,6 positions was nearly equal and occasionally was as high as the 3,4 positions. The 80% alcohol soluble material from

rye of 1 minute exposure in light and 100 minute exposure in the dark has been fractionated by extraction with benzene at pH 7.0, then continuous extraction with ether at pH 2.5 and finally fermentation of the sugars. On a percentage basis the isotope distribution was as follows (Italics are for dark fixation) benzene extract, 8.2 and 19.1, ether soluble acids, 6.9 and 49.2, sugars, 5.2 and 12.6, and fermentation residue, 79.2 and 17.4. Of the isotope administered 0.10 and 0.14% was fixed in the 80% alcohol extracts. The large amount of isotope in the residue fraction with light might be due to a unique photosynthetic product, however other interpretations will be considered.

D-amino acid formation occurrence and properties of an alanine racemase W. A. Wood* AND I. C. GUNSALUS *Lab. of Bacteriology, Indiana Univ., Bloomington*

The finding that *Streptococcus faecalis*, strain R, grown with vitamin B₆ contains D-alanine, whereas cells grown with D-alanine as replacement for vitamin B₆ do not form this vitamin, indicates a role of vitamin B₆ in D-alanine formation. Investigation of the mechanism of D-alanine formation has shown that a racemase is involved, for which pyridoxal phosphate serves as the co-enzyme. Vacuum dried cells of *S. faecalis*, strain R, harvested from a complex medium containing 0.3% cerelese, racemize 2 to 6 micromoles of alanine/mg cells/hr. A cell-free racemase was prepared from the dried cells by sonic oscillation and fractionated by ammonium sulfate precipitation and adsorption on and elution from calcium phosphate gel. Racemase activity was followed manometrically with L-alanine as substrate in the presence of excess D-amino acid oxidase. Both the vacuum dried cells and the cell-free enzyme were partially deficient in pyridoxal phosphate and the purified racemase was almost completely resolved. With the purified enzyme in the presence of pyridoxal phosphate, D- or L-alanine was converted to the racemic mixture. Other amino acids were not racemized by these preparations. Pyridoxamine phosphate did not act as a coracemase. Formation of alanine by transamination with amino acids or pyridoxamine phosphate and pyruvate did not occur, nor did pyruvate, α -ketoglutarate, or oxalacetate stimulate the rate of racemization. No pyruvate could be detected during racemization. Assay of representative bacterial species grown under various conditions indicates a wide distribution of alanine racemase. Attempts to demonstrate this enzyme in rabbit tissue homogenates have not revealed activity within the range of assay.

A study of non-competitive antagonism with chloromycetin and related analogs of phenylalanine

D. W. WOOLLEY *The Rockefeller Inst. for Med. Research, New York City*

The antibacterial effects of chloromycetin were found to be antagonized by phenylalanine. This amino acid was recognized to be a structural analog of the antibiotic agent, and to differ from it in 4 ways. Most of these types of change had previously been used individually to convert metabolites into substances which antagonized their action competitively. The antagonism of chloromycetin and phenylalanine was non-competitive and could be shown only within a restricted range of concentration of the antibiotic agent. In order to study the structural features which might confer on a competitive structural analog, a non-competitive type of action, phenylalanine was changed progressively one step at a time, by the introduction into it of the alterations which make it differ from chloromycetin. Thus, just the nitro group, or the dichloroacetyl radical, or the β -hydroxyl group, or the primary alcohol was built into phenylalanine, and then two, and then three, of these changes were made simultaneously. Tests with *Escherichia coli* and with *Lactobacillus casei* showed that the compounds which differed in only one respect from the metabolite were either inert as growth inhibitors, or were competitive antagonists of low potency. With two or three simultaneous alterations, more powerful antagonists were obtained, but with these the competitive feature was evident only at rather low concentrations. Large amounts were not reversed at all by phenylalanine. Chloromycetin, which has four structural dissimilarities to the metabolite, was strictly a non-competitive antagonist. These facts were viewed in relation to the understanding of non-competitive antagonism between structural analogs.

Evaluation of rates of metabolic processes from excretion data in isotopic feeding experiments HSIEN WU (introduced by EMMETT B. CARMICHAEL) *Biochemistry Dept., Med. College of Alabama, Birmingham*

When a labeled compound A is taken orally and the label is excreted in another compound B, the rate of appearance of B in urine depends on a) the rate of absorption of A from the alimentary canal, b) the rate of conversion of A to B in the metabolic pool and c) the rate of excretion of B by the kidneys. It is possible, therefore, to evaluate all these rates from the excretion data of labeled B after feeding the labeled compound A. On the assumptions that labeled and unlabeled molecules behave metabolically alike and that a steady state obtains, equations are formulated for the rates of absorption, conversion and excretion. The solution of these equations leads to an expression which relates the isotopic ratio of B excreted to the rate of absorption of labeled A.

(K), the rate of turnover of A (Q_A), the fraction of this rate due to conversion of A to B, the rate of turnover of B (Q_B) and the rate of excretion of B. The expression is complicated, but it can be easily solved by taking advantage of the fact that when Q_A is much smaller than K and Q_B , as it is in the case in isotopic feeding experiments, certain terms in the expression become negligible a few hours after feeding. Thus, Q_A can be very simply evaluated first after which the other rates can be evaluated. The expression arrived at in the present study puts the theory underlying the evaluation of rates on a sounder basis and at the same time makes the calculation simpler than hitherto.

Role of dietary proteins in development of sex organs of young rats under stimulus of a gonadotrophin RICHARD S. YAMAMOTO* AND BACON F. CHOW, *Dept. of Biochemistry, School of Hygiene and Public Health, Johns Hopkins Univ., Baltimore, Md.*

The development of sex organs under the added stimulus of a gonadotrophin involves the synthesis of tissue proteins which might be affected by dietary proteins. In this study, we fed *ad lib* 23 days old rats of both sexes, 5 diets containing 20% proteins of different nutritive values (casein, lactalbumin, soy bean, wheat gluten and stock diet). A 6th diet containing no protein was also included. On the 27th day, one half of the rats on each diet was given subcutaneously a daily dose of 10 units of Follutein (to males) or 0.10 unit of Gonadogen (to females). The remaining animals served as dietary controls. All animals were killed on the 33rd day. Their sex organs were removed, weighed and analyzed for total nitrogen. The results demonstrate 1) injection of gonadotrophin produced several-fold increase in the sex organs including those of animals on a nitrogen-free diet. Such growth obviously took place at the expense of other body tissues. 2) Injection of gonadotrophin to animals on diets containing proteins produced hypertrophy of the sex organs but a loss of body weight. 3) The degree of hypertrophy of sex organs was related to the nutritive values of the protein. 4) The ratios of weights of these organs to body weights at necropsy were significantly different depending on the dietary proteins. These data suggest that the response of normal rats to the stimulus of sex hormones is dependent on the protein intake.

Accumulation of a substance possessing niacin activity by a mutant strain of Neurospora CHARLES YANOFSKY* AND DAVID M. BONNER, *Osborn Botanical Lab., Yale Univ., New Haven, Conn.*

Although kynurenine and 3-hydroxykynurenine have been proposed as intermediates in the con-

version of tryptophan to niacin in *Neurospora* (BEADLE, G. W. ET AL. *Proc. Nat. Acad. Sci.* 33: 155, 1947; MITCHELL, H. K., AND J. F. NYC, *Proc. Nat. Acad. Sci.* 34: 1, 1948) evidence has not been presented as yet which would critically evaluate this hypothesis. The accumulation of either of these substances by mutant strains or their presence in culture filtrates or mycelial extracts has not been reported. To establish, with some degree of certainty, the participation of these compounds in the synthesis of niacin, their presence must be demonstrated. Niacin-less mutant strains capable of utilizing 3-hydroxyanthranilic acid, an established intermediate in niacin synthesis (BONNER, D. M. *Proc. Nat. Acad. Sci.* 34: 5, 1948), but incapable of using tryptophan, might be expected to accumulate kynurenine or 3-hydroxykynurenine. A mutant strain has been obtained which has these growth requirements and does accumulate large quantities of a substance possessing niacin activity. This substance has recently been isolated and tentatively identified as α -N-acetyl kynurenine. Its activity is too slight to justify considering it a normal intermediate in niacin synthesis. However, since this substance is structurally similar to kynurenine, it would seem reasonable to assume that the isolated compound results from kynurenine accumulation. This work clearly demonstrates the participation of kynurenine in the biosynthesis of niacin in *Neurospora*.

Analysis of commercial adrenal cortex extracts by paper partition chromatography ALEJANDRO ZAFFARONI, ROBERT B. BURTON AND E. HENRY KEUTMANN (introduced by ALEXANDER L. DOUNCE), *Depts. of Biochemistry and Medicine, Univ. of Rochester School of Medicine and Dentistry, Rochester, N. Y.*

In analyzing corticosteroid mixtures by the method of paper partition chromatography described previously by us (*Science* 111: 6, 1950), known compounds are required for use as standards. In order to use commercial adrenal cortex extracts as reference material, characterization of their major steroid components was undertaken. Analyzing relatively small quantities of extract, three commercial preparations were studied. The following α -ketolic steroids were found: 17-hydroxycorticosterone, 17-hydroxy-11-dehydrocorticosterone, corticosterone, 11-dehydrocorticosterone, and four other compounds whose probable identity will be discussed. Evidence for the presence of 11-desoxycorticosterone in very low concentration will be given. The various data to be presented in support of the identity of the compounds found will include chromatographic behavior of free and esterified forms, ultraviolet absorption spectra, absorption spectra of 2,4-dinitrophenylhydrazones, specific color reactions and formation of other derivatives.

Mechanism of oxidative deamination E A ZELLER, G A FLEISHER AND D C UTZ (introduced by M H POWER) *Division of Biochemistry, Mayo Foundation, Rochester, Minn*

The behavior of crude diamine oxidases (DO) from animal tissues, plants, (sprouting clover), molds (*Nocardia asteroides*) and bacteria were investigated. The substrates putrescine, cadaverine, histamine, agmatine, spermine, 1,3-diaminopropanol* (those with asterisks tried for the first time), 3-[aminobutyl]-pyridin,* and promin* were attacked with variable velocities by the DO from different sources. Similarly the degree of inhibition caused by pyridoxamine,* streptomycin, carbonyl reagents, pyocyanine, arcaine, 2-(4'-amino phenyl) piperidine* showed marked differences from one DO to another. Such enzymes like the DO from several sources will be designated 'homologous' in reference to the use of this term in comparative anatomy. The variations within a group of homologous enzymes may become of some importance for the understanding of the action of chemotherapeutic agents on the biochemical systems of microorganisms and their host respectively. The oxidation of diamines by *Nocardia* extracts was not followed by deamination, but the deamination took place by addition of DO-free extracts of rat kidney. These results are corroborated by those obtained with ophiol-L-amino acid oxidase. The reaction product from L-phenylalanine turned out to be different from phenylpyruvic acid, according to chemical, microbiologic and spectroscopic data. A model for the oxidative deamination in general and for DO specifically will be discussed.

Effects of anions, cations and amino acids on bovine alkaline phosphatases CHARLES A

ZITTLE AND EDWARD S DELLA MONICA * *Eastern Regional Research Lab, Philadelphia, Pa*

Alkaline phosphatase from intestinal mucosa of the calf and that from cow's milk were studied with phenylphosphate as the substrate. The phenol released by the enzymes was determined colorimetrically. About 0.1 mg of the milk preparation in a volume of 12 cc was required for an assay, $\frac{1}{25}$ th as much of the intestinal preparation was sufficient. Inhibition of the alkaline phosphatases by the following compounds was determined: the anions phosphate, arsenate, carbonate, tetraborate and pyrophosphate, the cations ethanolamine and ammonium, and the amino acids glutamic acid and lysine. The type of inhibition was determined with tetraborate, ethanolamine and the amino acids. From these studies and those of others, an inhibition pattern emerges that suggests that the milk and intestinal phosphatases differ. Milk phosphatase was more inhibited by the cations and by lysine than was the intestinal phosphatase, whereas the reverse was true with the anions and with glutamic acid. Our studies have shown that tetraborate was a competitive inhibitor, an effect shown by phosphate and carbonate also. Ethanolamine was a noncompetitive inhibitor, as was the ammonium ion. Inhibition by glutamic acid was largely noncompetitive, the small amount of competitive inhibition was no more than that shown by glycine. Lysine was also a noncompetitive inhibitor. Bodansky found that rat intestinal phosphatase was more inhibited by glutamic acid than were the bone and kidney phosphatases, the reverse was true of inhibition by lysine. Milk phosphatase is probably more closely related to bone and kidney phosphatases than it is to intestinal phosphatase.

AMERICAN SOCIETY FOR PHARMACOLOGY AND EXPERIMENTAL THERAPEUTICS

Fortieth Annual Meeting

ATLANTIC CITY, NEW JERSEY, APRIL 17-21, 1950

Histamine-like actions of curari on submaxillary glands of the cat JOHN ABAJIAN* AND N B DREYER *Depts of Anesthesiology and Pharmacology, Univ of Vermont, Burlington*

During the course of clinical anesthesia where D-tubocurarine is used to facilitate muscular relaxation one occasionally sees marked cyanosis and hypoxia in spite of adequate pulmonary ventilation. There is resistance to manual inflation even with an intratracheal catheter in place. This would seem to indicate obstruction in the lower respiratory tract, reputedly due to bronchospasm from histamine liberated on injection of curari. Histamine is also liberated from the tissues of the forearm on intra-arterial injection of curari. The use of anti-histaminic drugs to combat this curari shock—bronchoconstriction and hypotension—has been suggested. To test this hypothesis the submaxillary gland of the cat was used. This gland secretes saliva on intra-arterial injection of histamine. Actions of Histamine and D-tubocurarine were compared. In cats under chloralose, (100 mg/kg) the salivary ducts were cannulated and the chorda tympani and cervical sympathetic were sectioned. All drugs were given intra-arterially into the common carotid in amounts never exceeding 25 cc total dose. Artificial respiration was maintained in all experiments. Histamine, 10-20 μ g and D-tubocurarine, 25-60 μ g, caused a flow of saliva. D-tubocurarine on repeated injections gave lessened responses. Anti-histaminics like Thonzylamine and Neo-antergan abolished the salivary responses to both histamine and D-tubocurarine. In addition D-tubocurarine caused ganglionic block shown by stimulating the nerves of the gland. These results would seem to support the hypothesis that the injection of D-tubocurarine liberates histamine from the tissues.

Effect of morphine in vivo and in vitro on glycolysis of rat tissues L G ABOOD (introduced by J M COON) *Dept of Pharmacology, Univ of Chicago, Chicago, Ill*

Glycolysis was studied on tissues of rats which were chronically and acutely treated with morphine. The chronically morphinized rats were given morphine SQ daily for a period of 10 weeks with progressively increasing doses up to 250

mg/kg. Acutely treated animals were given 50 mg/kg morphine 3 hours before they were killed. The rate of glycolysis from glucose, as determined by CO_2 and lactic acid formation, increased 65% in the chronically treated animals and 50% in the acutely treated animals. A linear relationship between the dose of morphine and the increase in glycolysis was found in animals acutely treated. This increase in glycolysis was observed in brain, liver and kidney of acutely and chronically treated animals and the skeletal muscle of chronically treated animals only. With a final concentration of 10^{-3} M morphine sulfate a 50% activation of glycolysis was produced *in vitro* in all these tissues except skeletal muscle, in which no change was noted. The mechanism of action of this increased glycolysis has not been elucidated to date. Morphine was tested *in vitro* on hexokinase, aldolase, ATP-ase, and lactic dehydrogenase, and was found to be without effect. An increase of aldolase was found in the tissues of chronically morphinized animals, but it was not enough to account for the increased glycolysis. Morphine is oxidized anaerobically *in vitro*, possibly to pseudomorphine, and the effect of this reaction on glycolysis is now being considered.

Comparison of central and peripheral nervous system effects of certain anti-muscarinic local anesthetic agents BENEDICT E ABREU, FREDERICK H MEYERS* AND WILLIAM M ALEXANDER* *Research Dept, Pitman-Moore Co, Indianapolis, Ind, and Division of Pharmacology and Experimental Therapeutics, Univ of California Med School, San Francisco, Calif*

Previous observations (Federation Proc 5 161, 1946) indicated that certain anti-muscarinic compounds administered in non-lethal dosage produced effects which could be construed as being due to central nervous system stimulation. However, it was also shown in this investigation that the central nervous system effects of agents known to be stimulant in the dog and other mammals could not be differentiated from those produced by anti-muscarinic agents, which uniformly caused ataxia and muscular weakness in the dog. Amino alcohol esters of the following acids have been studied: tropic, mandelic, phenyl- α thienylgly

colic, fluorene - 9 - carboxylic, diphenylacetic, 1-phenyl cyclopentane-1-carboxylic and 4 n-hexyloxy benzilic. All were less effective than atropine in depressing intestinal motility or the pupillary response to light. However, all were more capable than atropine of producing skeletal muscular weakness and ataxia. Though all of these agents possess local anesthetic activity, no correlation appears to exist between this type of action and such central nervous system depressant effects as ataxia and skeletal muscular weakness.

Some effects of procaine and diethylaminoethanol in auricular flutter in the dog G. H. ACHESON AND BARBARA BROWN * *Pharmacology Dept., Univ. of Cincinnati College of Medicine, Cincinnati, Ohio*

In dogs under dial-urethane anesthesia, with chest open and artificial respiration, stable auricular flutter was established by the method of Rosenblueth and García Ramos. Auricular electrograms and ECG's were recorded. In vagotomized animals procaine (1-8 mg/kg) slows the rate of auricular flutter with little change of ventricular rate, whereas diethylaminoethanol (16-64 mg/kg) slows both auricular and ventricular rates. Both compounds slow conduction velocity in the non-fluttering auricle. Reversion from flutter to sinus rhythm occurs less regularly and at lower auricular rates with procaine than with diethylaminoethanol. At doses of the 2 compounds which produce equivalent slowing of rate of auricular flutter (1 and 32 mg/kg, respectively), the 'maximal rate' of the non-fluttering auricle *in situ* is decreased less by procaine than by diethylaminoethanol. In animals with intact vagi the slowing of the rate of auricular flutter produced by procaine is accompanied by an increase of ventricular rate, whereas diethylaminoethanol slows both auricle and ventricle as above. Stimulation of the cut vagus accelerates the rate of auricular flutter and markedly decreases the ratio of ventricular rate to auricular rate. These effects are largely suppressed by procaine, but only occasionally decreased by diethylaminoethanol.

Analeptic effect of succinate, malonate, citrate and acetate on pentobarbital sodium JOSEPH P. ADAMS, JR. * AND EDWARD LARSON *Dept. of Physiology and Pharmacology, Univ. of Miami Med. Research Unit at Veterans' Hospital, Coral Gables, Fla.*

Certain compounds suggested by Soskin and Taubenhaus and others (*J. Pharmacol. & Exper. Therap.* 78:49, 1943, *Ibid.* 83:45, 1945) for analeptic activity, and other carbohydrate like compounds have been studied. Male Wistar rats, properly nourished, weighing 150-350 gm each were fasted 15-17 hours. The control group (29 rats) which received sodium pentobarbital 50 mg/

kg injected subcutaneously, averaged 100 minutes for duration of anesthesia and 142 minutes for duration of the loss of the righting reflex. No rats were used more frequently than once a month to avoid tolerance. The test groups each received an additional intraperitoneal injection of sodium succinate, sodium malonate, sodium citrate or sodium acetate, 1 gm/kg, as a 10% solution. The latter injections were made simultaneously with the pentobarbital. To determine the onset of and recovery from anesthesia, the paw of one of the extended hind legs was stimulated by a pinch at 2-minute intervals. Statistical analysis (J. H. BURN *Biological Standardization* 1937, p. 29) showed that succinate had a slight analeptic effect if any ($S.D. = 3.02$ for 28 rats) on the duration of anesthesia, while acetate showed a marked effect ($S.D. = 3.02$ for 28 rats) on the duration of anesthesia. None of the salts used had any significant effect on the duration of the loss of the righting reflex induced by pentobarbital except citrate which prolonged it significantly.

Comparative effects of epinephrine and arterenol-isopropyl arterenol mixtures RAYMOND P. AHLQUIST *Dept. of Pharmacology, Univ. of Georgia School of Medicine, Augusta*

It has been repeatedly demonstrated that although epinephrine is less active than arterenol as a pressor agent it is more active as an excitatory agent (vasoconstriction, uterine stimulation, contraction of retractor penis and nictitating membrane, etc.). One explanation for the smaller pressor effect of epinephrine is that unlike arterenol it is a very active vasodilator, and that this vasodilation diminishes its pressor effect. To test this theory various mixtures of racemic arterenol and isopropyl-arterenol were compared with racemic epinephrine on the arterial pressure, femoral arterial blood flow, and uterine and intestinal activity in the anesthetized dog. The following mixtures were compared with 0.001 M epinephrine.

MIXTURE	ARTERENOL	ISOPROPYL ARTERENOL
1	0.002 M	0.0005 M
2	0.003 M	0.0005 M
3	0.002 M	0.0003 M

Mixture 3 most closely approximated epinephrine. The most obvious difference was noted in the duration of the pressor response, the mixtures showed a more rapid decline from the pressure peak. This can be explained in part by different rates of inactivation of the 3 amines. These results give support to the theory that the pressor response to epinephrine is diminished by its simultaneous vasodilating action.

Cardiovascular and respiratory effects of β -diethylaminoethyl 4 n-hexyloxybenzilate HCl
 WILLIAM M. ALEXANDER AND WILLIAM K. McDONALD (introduced by BENEDICT E. ABREU)
Research Dept., Pitman-Moore Co., Indianapolis, Ind.

The cardiovascular and respiratory effects produced by intravenous administration of β -diethylaminoethyl 4 n-hexyloxybenzilate, a new local anesthetic, were studied and compared with dibucaine in both unanesthetized and anesthetized dogs. The effects produced by both drugs paralleled each other very closely. In general, the hexyloxybenzilate was one tenth as active as dibucaine in producing cardiovascular and respiratory effects. In unanesthetized dogs, 1.0–3.0 mg/kg of the benzilate ester produced a moderate increase in cardiac rate, smaller doses had no apparent effect. When 5.0 mg/kg or more was given, cardiac arrhythmias and a progressive decrease in heart rate resulted. Respiration was unaffected by doses of 3.0 mg/kg or less. Doses of 5.0 mg/kg or more often caused the animal to pant. Both drugs exerted a powerful vasodepressor action in dogs anesthetized with ether. The duration and degree of vasodepression was directly related to dosage. These blood pressure changes were not produced by vagal or other cholinergic stimulation, since they were not altered by bilateral vagotomy or adequate atropinization. With a dose of 1.0 mg/kg of the benzilate ester, there was a moderate increase in heart rate. After doses of 3.0–10.0 mg/kg there was a progressive decrease in heart rate which was associated with arrhythmias and transitory heart blocks. Identical effects are produced by doses of dibucaine about one tenth as great. Accordingly, these drugs appear to be direct cardiac depressants. Both respiratory rate and depth were decreased by vasodepressor doses of these drugs. Fatal doses appear to cause respiratory failure.

Effect of rutin and related compounds on experimental frostbite in rabbits ANTHONY M. AMBROSE, DOROTHY J. ROBBINS* AND FLOYD DEEDS
Pharmacology Division, Bureau of Agricultural and Industrial Chemistry, Agricultural Research Administration, U. S. Dept. of Agriculture, Albany, Calif.

Following the demonstration by Fuhrman and Crismon (*J. Clin. Investigation* 27: 364, 1948) that orally administered rutin was effective on experimental frostbite in rabbits, similar studies were undertaken by us with rutin and related flavonoids. Experimental frostbite was produced in rabbits by the technique described by Fuhrman and Crismon. The various flavonoids were administered by stomach tube, one dose (100 mg/kg) immediately after freezing and daily doses on 3

following days. In 12 rabbits receiving rutin we have confirmed the observations of Fuhrman and Crismon. Other flavonoids—quercitrin (7 rabbits), quercetin (7), methyl hesperidin chalcone (4), 2-3-dihydroquercetin (6), and an extract of muscat raisin seeds (7) (prepared by Dr. C. E. Sando of this Bureau) all appeared to offer some degree of protection as compared to no protection in 20 controls. In the untreated rabbits tissue loss was the greatest, most of the frozen foot was involved. In the flavonoid-treated rabbits loss to the frozen foot was confined chiefly to the toes, with partial to complete loss of phalanges, and in a few instances with slight scarring of the dorsum. The suggestion of Fuhrman and Crismon that the protection afforded by rutin may be due to changes in the pattern of local blood flow may also be applicable to the other flavonoids studied on frostbite, and on the trypan blue escape time previously reported by us (*J. Pharmacol. & Exper. Therap.* 97: 115, 1949).

Release of nucleic acids from cell components by heparin NORMAN G. ANDERSON AND KARL M. WILBUR (introduced by FREDERICK BERNHEIM)
Dept. of Zoology, Duke Univ., Durham, N. C.

Heparin in low concentration has been found to increase the viscosity of rat liver brei, while high concentrations caused gelation. Removal of the nuclei from the brei prevented the observed increase in viscosity. Suspensions of nuclei exhibited an increase in viscosity on the addition of heparin further indicating that the nuclei were responsible for the viscosity increase of the brei. After centrifugal removal of the nuclei, desoxyribonucleic acid (diphenylamine reaction) was found in the supernate. Similar experiments with purified isolated mitochondria indicated that heparin causes the release of ribonucleic acid (orcinol reaction) without increasing viscosity. It is suggested that heparin with its strongly acidic sulfonic acid groups may displace nucleic acids from the basic proteins of the nucleus and the mitochondria. Dilute rat liver homogenates in sucrose-phosphate solution (pH 7.15) reached a maximum viscosity 4–8 minutes after the addition of heparin (70 μ g/ml, 23° C). The viscosity then fell, indicating depolymerization by enzyme action. The findings are discussed in relation to the inhibitory effect of heparin on cell division and the possible significance of high concentrations of heparin in the blood.

Anti-curare activity of 3-acetoxy phenyltrimethylammonium methylsulfate (Nu-2017) in man
 JOSEPH F. ARTUSIO, JR.,* WALTER F. RIKER, JR. AND W. CLARKE WESCOE
Depts. of Surgery (Anesthesia) and Pharmacology, Cornell Univ. Med. College and New York Hospital, New York City

Previous reports have described the pharmacology of Nu-2017 (*J Pharmacol & Exper Therap* 97 190, 208, 1949). The potent anti-curare action of this compound, previously described in cats, has now been demonstrated in man. Anesthetized surgical patients were given intravenous doses of D-tubocurarine chloride sufficient to reduce their respiratory minute volumes (RMV) to 40-60% (A), 20-40% (B), or 0-20% (C), of the control values. At the points of deepest curarization, various doses of Nu-2017 were given intravenously. The anti-curare action was evident within one minute, and maximal within 2, in every patient regardless of the dose of Nu-2017 injected or the depth of curarization. In the patients of group A a dose of 5.0 mg of Nu-2017 was sufficient to restore the RMV to the control level where it remained. In the patients of group B a Nu-2017 dose of 5.0-10.0 mg increased the RMV to approximately 80% of control. A second smaller dose restored the RMV to the control level. In the patients of group C a dose of 5.0 or 7.5 mg of Nu-2017 did not produce adequate ventilation although repetition of the dose produced a prompt restoration of the RMV to approximately 80% of control. In this group a large dose (15.0 mg) raised the RMV to over 60% of control where it remained constant, a second smaller dose of Nu-2017 returned the RMV to control. The only significant side-effect was a moderate cardiac slowing with the higher doses. None of these doses produced any signs of synergism with curare. The anti-curare action of related agents will be discussed.

Chemo- and pressor-reflexes from perfused heart and lungs of dogs DOMINGO M. AVIADO, JR., T. H. LI, W. KALOW, M. HESS and G. TURNBULL (introduced by C. J. LAMBERTSEN) *Lab of Pharmacology, Univ of Pennsylvania, Philadelphia*

Previous reports of reflexes from the heart and pulmonary circulation have been the subject of controversy chiefly because of the methods used. This investigation was undertaken using methods that we believe are less objectionable. With the aid of perfusion pumps and one or more donor dogs, each part of the cardio pulmonary circulation was perfused individually so that the flow, pressure and gas contents of the blood could be kept under reasonably complete control. Each factor could then be independently changed without directly affecting respiration and circulation. Veratridine which stimulates reflexes (*Federation Proc* 8 5 1949) was used for testing intact innervation of the perfused organ. Although veratridine still reflexly inhibited respiration and circulation through apparent chemoreceptors in the perfused lung, no chemo reflex sensitive to changes

in blood oxygen and CO₂ was demonstrable. Pulmonary congestion caused a reflex drop in systemic blood pressure and reflex inhibition of respiration. These receptors appear to be in the pulmonary veins and are connected centrally by the ipsilateral vagus. Raising pressure in the right side of the heart caused a bradycardia, contrary to the report of Bainbridge and others. There was an accompanying drop in systemic blood pressure independent of bradycardia. After vagotomy, the bradycardia disappeared and tachycardia appeared instead. There was a powerful reflex bradycardia from raising pulmonary arterial trunk pressure, also dependent on an intact vagus.

Hypothermic agents. II Effects on pyruvate utilization by brain JAMES A. BAIN AND R. M. KOHLENBRENNER (introduced by C. C. PFEIFFER) *Depts of Psychiatry and Pharmacology, Univ of Illinois College of Medicine, Chicago*

The effects of 3 hypothermic drugs were tested on fortified rat brain homogenates which were capable of uptakes of 10 microatoms of oxygen, 10 micromoles of pyruvate or oxalacetate and 20-30 μ M of inorganic phosphorus/50 mg (wet weight) tissue/30 min with P/O ratios of approximately 2.5. B-45 (4-amyln N-benzohydril pyridinium bromide) gave 50% inhibition of the system at 10^{-5} M, Privityne (alpha naphthyl methyl imidazoline HCl) at 5×10^{-4} M, and pyruvamide at concentrations twice the concentration (18 mM) of the pyruvate used as substrate. Inhibition of carbohydrate metabolism at this level is suggested as a possible mechanism of action of these agents in lowering body temperature.

A rapid and simple method for carbon dioxide analysis in anesthetic atmospheres ANN BARDEEN* AND O. S. ORTH *Depts of Anesthesia and Pharmacology, Univ of Wisconsin Med School, Madison, Wis*

Methods in general use for the analysis of carbon dioxide in anesthetic atmospheres have required either the transfer of gas samples to the apparatus or the use of quite complicated electronic instruments. By adaptation of the 'pocket model' of the Dwyer CO₂ indicator, made commercially for testing flue gas, it has been possible to obtain analyses in 30-60 seconds. The method is essentially a manometric procedure for measuring absorption of CO₂ by alkali. The samples are taken directly into the apparatus from the mixture in the breathing bag, mask, pharynx, or trachea of anesthetized patients. The accuracy has been determined by comparison with the Van Slyke manometric method. In the operating room, the apparatus has been used to study the elimination of CO₂ during anesthetic administrations, with a variety of techniques and with different rates of

gas flow Preliminary results indicate the practical utility of this instrument where rapid, simple analyses of CO_2 are desired Other applications of use for this compact, convenient analyser will be the study of the effect of altered metabolic states and decreased respiratory exchange on carbon dioxide elimination, the determination of the exhaustion of carbon dioxide absorbents, and the measurement of CO_2 accumulation in incubators and oxygen tents

Electrical action of adrenergic blocking agents

T C BARNES *Dept of Pharmacology, Hahnemann Med College and Hospital of Philadelphia, Philadelphia, Pa*

Sympathomimetic drugs are soluble in tri-glyceride oils on which parasympathomimetic drugs are inactive (*Science* 104 569, 1946, *Federation Proc* 8 272, 1949) Tyramine is used to detect adrenergic oils (0.05% gives a phaseboundary potential of 60 mv negativity on tributyrin) Adrenolytic drugs tested dissolve in adrenergic oils and establish a negative phaseboundary potential which blocks sympathomimetic agents by competitive inhibition 5 mg % veriloid (Coe Chemical) gave 60 mv negativity on equal parts triacetintributyrin suggesting that the *Veratrum viride* alkaloids probably reduce blood pressure by action on sympathetic nerve endings 0.05% C-7337 or 2-(N-p' - tolyl-N (m-hydroxyphenyl)-aminoethyl)-imidazole HCl has outstanding phaseboundary potential producing 136 mv negativity on tributyrin (compared with 45 mv for priscoline) Benodane or 2(1-Piperidylmethyl)-1,4-Benzodioxan produced 60 mv negativity on tributyrin (which however returned to zero in 15 minutes) A sympathetic cellular receptor was represented by a narrow tube of triacetin 3 mm in diameter on which 0.125% dibenamine produced the same potential (46 mv) as on a wide surface of triacetin 16 mm in diameter Drug molecules dissolved in a spot on a living cell would produce the same potential as when spread over the entire surface When the model receptor contained F dibenamine, benzedrine and other sympathomimetic drugs were without effect

Effect of carbon dioxide on phaseboundary potential of acetyl-beta-methylcholine in the presence of brain esterase

T C BARNES *Dept of Pharmacology, Hahnemann Med College and Hospital of Philadelphia, Philadelphia, Pa*

Five mg % of methacholine in Locke's solution containing 12 mg % bicarbonate (pH 8.0) gave phaseboundary potential of 25 mv negativity at a guaiacol interface in the oil-cell (*Science* 104 569, 1946) Five gm of fresh ground dog cerebral cortex was placed in each of two 400 cc portions which were stirred for 6 hours at 27°C with CO_2
